Compressed-Sensing Recovery of Images and Video Using Multihypothesis Predictions

Chen Chen, Eric W. Tramel, and James E. Fowler

Abstract—Compressed-sensing reconstruction of still images and video sequences driven by multihypothesis predictions is considered. Specifically, for still images, multiple predictions drawn for an image block are made from spatially surrounding blocks within an initial non-predicted reconstruction. For video, multihypothesis predictions of the current frame are generated from one or more previously reconstructed reference frames. In each case, the predictions are used to generate a residual in the domain of the compressed-sensing random projections. This residual being typically more compressible than the original signal leads to improved reconstruction quality. To appropriately weight the hypothesis predictions, a Tikhonov regularization to an ill-posed least-squares optimization is proposed. Experimental results demonstrate that the proposed reconstructions outperform alternative strategies not employing multihypothesis predictions.

I. INTRODUCTION

The compressed sensing (CS) of images and video faces several challenges including a large computational cost associated with multidimensional signal reconstruction and a huge memory burden when the random sampling operator is represented as a dense matrix. To address these issues, structurally random matrices (SRMs) (e.g., [1]) can be used to provide a sampling process with little computation and memory. An alternative to SRMs is to limit CS sampling to relatively small blocks (e.g., [2, 3]). Block-based CS (BCS) with smoothed projected Landweber reconstruction (BCS-SPL) [3], as well as a multiscale variant (MS-BCS-SPL) [4] deployed in the domain of a discrete wavelet transform (DWT), typically provides much faster reconstruction than techniques based on full-image CS sampling. For video, a motion-compensated reconstruction (MC-BCS-SPL) [5] extends this advantage to the CS reconstruction of video in which one or more frames are used to make predictions of the current frame such that the resulting residual is more efficiently reconstructed.

In this paper, we extend this concept of prediction plus residual reconstruction to the use of multihypothesis (MH) predictions (e.g., [6]). That is, we couple BCS-SPL with MH predictions for both still-image as well as video reconstruction. For video, we cull the multiple hypothesis predictions from previously reconstructed frames. For still images, we first reconstruct the image with an initial BCS-SPL reconstruction, cull predictions for each image block from spatially surrounding blocks, and then finally reconstruct the resulting prediction-residual image. We also consider a similar multiscale variant in which the MH predictions occur in the wavelet domain.

In all cases, we determine the MH predictions in the domain of CS random projections. Due to the ill-posed nature of the resulting prediction problem, we apply Tikhonov regularization [7] to arrive at a solution. Experimental results for video demonstrate that this Tikhonov-regularized reconstruction usually provides higher PSNR as compared to a similar $\ell_1$-regularized approach [8, 9], as well as compared to a straightforward intraframe BCS-SPL reconstruction. The same Tikhonov-regularized reconstruction is then applied to the MH-based still-image reconstruction; corresponding experimental results indicate a significant gain in PSNR as compared to the original BCS-SPL as well as to a popular still-image reconstruction based on total-variation (TV) minimization [10].

II. BACKGROUND

Suppose we want to recover real-valued signal $x \in \mathbb{R}^N$ from $M$ measurements such that $M \ll N$; i.e., $y = \Phi x$, where $y \in \mathbb{R}^M$, and $\Phi$ is an $M \times N$ measurement matrix with subsampling rate, or subrate, being $S = M/N$. CS theory holds that, if $x$ is sufficiently sparse in some transform basis $\Psi$, then $x$ is recoverable from $y$ by the optimization,

$$\hat{x} = \arg \min_{x \in \mathbb{R}^N} \|\Psi x\|_1, \text{ such that } y = \Phi x,$$

as long as $\Phi$ and $\Psi$ are sufficiently incoherent, and $M$ is sufficiently large. High-dimensional signals, such as a images or video, impose a huge memory burden when explicitly storing the sampling operator $\Phi$ as a dense matrix. In addition, the reconstruction process will be time consuming if the dimensionality is large. To assuage the computation complexity, in [2, 3], an image is partitioned into smaller blocks while sampling is applied on a block-by-block basis. In such BCS, the global measurement matrix takes a block-diagonal structure, $\Phi = \text{diag}(\Phi_B, \ldots, \Phi_B)$, wherein $\Phi_B$ independently samples blocks within the image. That is, $y_i = \Phi_B x_i$, where $x_i$ is a column vector with length $B^2$ representing block $i$ of the image, and $\Phi_B$ is a $M_B \times B^2$ measurement matrix such that the subrate of BCS is $S = M_B/B^2$. In [2, 3], reconstruction uses a procedure that couples projected Landweber (PL) iteration with a smoothing operation intended to reducing blocking artifacts. The overall technique was called BCS-SPL in [3].

BCS-based techniques such as BCS-SPL that rely on a block-based sampling operator can be at a disadvantage in terms of reconstruction quality since CS sampling generally...
works better the more global it is. To improve reconstruction quality, in [4], BCS-SPL was deployed independently within each subband of each decomposition level of a wavelet transform of an image to provide multiscale sampling and reconstruction; the resulting algorithm for image reconstruction was called MS-BCS-SPL.

For video, one can simply apply a CS image sampling and reconstruction independently frame by frame (i.e., “intraframe” CS sampling and reconstruction). Alternatively, one can incorporate motion estimation (ME) and motion compensation (MC) into the CS reconstruction of video while maintaining the same frame-by-frame image sampling (e.g., [5, 8, 9, 11, 12]). In the latter approach, a motion-compensated prediction of the original frame can be made from a reference frame, wherein some initial reconstruction, \( x \), is unknown in CS reconstruction, solving (2) directly is infeasible. Instead, one approach is to reformulate (2) as

\[
\hat{x} = \arg \min_{p \in \mathcal{P}(x_{ref})} \| x - p \|_2^2 ,
\]

(2)

where \( \mathcal{P}(x_{ref}) \) is the set of all ME/MC predictions that can be made from a reference frame, \( x_{ref} \). However, since \( x \) is unknown in CS reconstruction, solving (2) directly is infeasible. Instead, one approach is to reformulate (2) as

\[
\hat{x} = \arg \min_{p \in \mathcal{P}(x_{ref})} \| \hat{x} - p \|_2^2 ,
\]

(3)

wherein some initial reconstruction, \( \hat{x} \), is used as a proxy for \( x \) in (2); this is, in fact, the approach taken in [5, 12].

An alternative is to recast the optimization of (2) from the ambient signal domain of \( x \) into the measurement domain of \( y \); specifically,

\[
\hat{x} = \arg \min_{p \in \mathcal{P}(x_{ref})} \| y - \Phi p \|_2^2 .
\]

(4)

The Johnson-Lindenstrauss (JL) lemma [13] holds that \( L \) points in \( \mathbb{R}^N \) can be projected into a \( K \)-dimensional subspace while approximately maintaining pairwise distances as long as \( K \geq O(\varepsilon^{-2} \log L) \) for any \( 0 < \varepsilon < 1 \). This suggests that the solution of (4) will likely coincide with that of (2). The next section explores two general strategies for implementing (4) with MH prediction.

### III. MULTIHYPOTHESIS PREDICTIONS FOR VIDEO

#### A. MH with Tikhonov Regularization

For a MH CS reconstruction of video, the goal is to reformulate (4) so that, instead of choosing a single prediction, or hypothesis, we find an optimal linear combination of all hypotheses contained in some search set; i.e., (4) becomes

\[
\tilde{w}_{t,i} = \arg \min_{w} \| y_{t,i} - \Phi H_{t,i}w \|_2^2 ,
\]

(5)

and we have also recast (4) for block-based prediction with \( i \) being the block index and \( t \) being the temporal frame index. Here, \( H_{t,i} \) is a matrix of dimensionality \( B^2 \times K \) whose columns are the rasters of the possible blocks within the search space of the reference frames. In this context, \( \tilde{w}_{t,i} \) is a column vector which represents a linear combination of the columns of \( H_{t,i} \). However, because \( M \ll K \), the ill-posed nature of the problem requires some kind of regularization in order to differentiate among the infinite number of possible linear combinations which lie in the solution space of (5).

The most common approach to regularizing a least-squares problem is Tikhonov regularization [7] which imposes an \( \ell_2 \) penalty on the norm of \( \tilde{w}_{t,i} \),

\[
\hat{w}_{t,i} = \arg \min_{w} \| y_{t,i} - \Phi H_{t,i}w \|_2^2 + \lambda \| \Gamma w \|_2^2,
\]

(6)

where \( \Gamma \) is known as the Tikhonov matrix; this strategy for MH prediction was initially proposed in [11]. The \( \Gamma \) term allows the imposition of prior knowledge on the solution—we take the approach that hypotheses which are the most dissimilar from the target block should be given less weight than hypotheses which are most similar. Specifically, we propose a diagonal \( \Gamma \) in the form of \( \Gamma_{j,j} = \| y_{t,i} - \Phi h_{t,j} \|_2^2 \), where \( h_{t,j} \) are the columns of \( H_{t,i} \), \( j = 1, \ldots, K \). For each block then, \( \hat{w}_{t,i} \) can be calculated directly by the closed form solution,

\[
\hat{w}_{t,i} = \left( \Phi H_{t,i}^T \Phi H_{t,i} + \lambda^2 \Gamma^2 \Gamma \right)^{-1} \Phi H_{t,i}^T y_{t,i} ,
\]

(7)

#### B. MH with \( \ell_1 \) Regularization

An alternate to the Tikhonov regularization used in (6) was suggested in [8, 9]. Specifically, it was assumed in [8, 9] that the MH weights \( \hat{w}_{t,i} \) in (5) are sparse; i.e., only relatively few of the possible hypotheses in \( H_{t,i} \) should contribute the prediction. As a consequence of this assumption, the reconstructions in [8, 9] essentially impose an \( \ell_1 \) penalty term on \( \hat{w}_{t,i} \); i.e.,

\[
\hat{w}_{t,i} = \arg \min_{w} \| \Phi H_{t,i}w - y_{t,i} \|_2^2 + \lambda \| w \|_1 .
\]

(8)

The intuition here is that only a few blocks within the search space contribute significantly to the linear combination. However, in the context of CS reconstruction, a regularization enforcing sparsity is needlessly restrictive on the structure of \( \hat{w}_{t,i} \), which can potentially result in lower prediction quality. Furthermore, Tikhonov regularization in the form of (6) is a much more amenable solution than \( \ell_1 \) regularization in terms of scalability and computation time, as well—with the \( \ell_1 \) penalty, the optimization in (8) is approached as a traditional
CS problem using some generic CS solver independently on each block, while Tikhonov regularization simply uses (7).

IV. MULTIHYPOTHESIS PREDICTIONS FOR IMAGES

A. MH-BCS-SPL

Above, we considered the use of MH prediction for the CS of video. We now consider applying MH prediction for the CS of a still image. Specifically, suppose image $x$ is split into blocks of size $B \times B$ in BCS; each block is further divided into subblocks of size $b \times b$. MH predictions are created for each individual subblock of the block by sliding a $b \times b$ mask across the entire search window to create all candidate predictions for each subblock. Since the block size is $B \times B$, the region in the block outside of the $b \times b$ subblock is set to all zeros; the resulting $B \times B$ “zero-padded” block is then placed as a column in $H_i$. $H_i$ thus contains all the predictions for all of the subblocks of block $i$. This subblock-based MH-prediction process is illustrated in Fig. 1(a)–(c).

The parameter $\lambda$ in (9) controls the regularization. Unfortunately, there does not appear to be a straightforward approach for finding an optimal value without foreknowledge of $x$. Some possible approaches to choose an appropriate $\lambda$ include the L-curve, generalized cross validation, and the discrepancy principle. Through empirical analysis, we test a set of $\lambda$ values and choose the one gives the best performance.

We incorporate the proposed MH-based prediction into BCS-SPL image reconstruction, resulting in a technique we call MH-BCS-SPL (see Algorithm 1). In MH-BCS-SPL, MH prediction and residual reconstruction are repeated with increasing subblock size in order to improve the quality of the recovered image.

Specifically, the original BCS-SPL reconstruction of [3] uses a block size of $B = 32$ and a dual-tree DWT (DDWT) [14] as the sparsity transform $\Psi$. In MH-BCS-SPL, we start with an initial subblock size of $b = 16$ and an initial search window of $w = 8$. The subblock size $b$ and search window $w$ are increased based on a criterion involving structural similarity (SSIM) [15]. As a stopping criterion, we apply cross validation [16] to predict the performance. Specifically, three measurements as a holdout set $\mathcal{H}_i$ are used for the performance test. For example, at subrate $= 0.1$ and block size $B = 32$, the measurement matrix $\Phi \in \mathbb{R}^{1024 \times 1024}$ has three more rows than $\Phi_H \in \mathbb{R}^{99 \times 1024}$ which is used for reconstruction. $\Phi_H \in \mathbb{R}^{99 \times 1024}$ is the measurement matrix for the holdout set. In other words, $\Phi = [\Phi_R; \Phi_H]$. The residual calculated in the projected domain is

$$R = \|\Phi_H x - \Phi_H \hat{x}\|_2 = \|y - \Phi_H \hat{x}\|_2.$$  

This means that, if $\hat{x}$ is close to $x$, then $R$ should be small.

B. MH-MS-BCS-SPL

As described in [4], MS-BCS-SPL performs both CS measurement and reconstruction in the wavelet domain; i.e., the CS measurement process becomes $y = \Phi \Omega x$, where $\Omega$ is a 3-level DWT with the popular 9/7 biorthogonal wavelet. Block size depends on transform level, with $B_l = 16, 32,$ and 64 for levels $l = 1$, 2, and 3, respectively ($l = 3$ is the highest-resolution level). A DDWT is again used as a sparsity transform $\Psi$.

We now formulate a MH version of MS-BCS-SPL by performing MH predictions within the wavelet domain. That is, in MH-MS-BCS-SPL, multiple predictions for a block are made using the procedure of Fig. 1(a) applied in the wavelet domain of the MS-BCS-SPL reconstructed image. In the case that the subblocks are smaller than the block size (i.e., $b_l < B_l$), the MH predictions are carried out within a subband of a DWT. However, for the $b_l = B_l$ case, predictions are calculated using a redundant DWT (RDWT) for $\Omega$. Such a RDWT is an overcomplete transform, effectively created by eliminating downsampling from the traditional DWT; see, e.g., [17]. In this latter case, multiple hypotheses are culled from the various RDWT phases associated with the subband as illustrated in Fig. 1(d).

In our experiments, $\lambda = 0.035$ is used when $b_l < B_l$, and $\lambda = 0.5$ when $b_l = B_l$. The initial subblock size $b_l$ is one eighth of the block size $B_l$ at each decomposition level. The initial search window is set to $w = 1$. For the stopping criterion, we did not apply cross validation, as we found that the reduced number of measurements $y$ due to the holdout set would adversely affect the recovery performance since CS sampling is deployed in the wavelet domain. In this case, a threshold $\tau_{\ell}$ is calculated from the SSIM between two successive residual reconstructed images is used as a stopping criterion: $\tau_{\ell} = 0.99995$ when subrate $= 0.1, 0.2,$ and 0.3; $\tau_{\ell} = 0.99995$ when subrate $= 0.4$ and 0.5. Algorithm 2 details the MH-MS-BCS-SPL procedure.

V. RESULTS

A. Video

We consider the first three consecutive frames, $x_1$, $x_2$, and $x_3$ of a given video sequence—the first and third frames,
Algorithm 2 MH-MS-BCS-SPL

Input: $y, \Phi, \Psi, \hat{x}, L = 3, \{b_l\}, w, \{B_l\}, \tau_s$
Output: $\hat{x}$
Initialization: $i = 1, \hat{x}_0 = \bar{x}, s_0 = 0$
repeat
    if $b_l = B_l$ for each level $l$ then
        $\hat{x}_l = \Omega$RDWT$\hat{x}$ \{Perform redundant wavelet transform\}
    else
        $\hat{x}_l = \Omega$DWT$\hat{x}$ \{Perform discrete wavelet transform\}
    end if
    for $1 \leq l \leq L$ do
        $\hat{x}(\theta) = $ MH_Prediction($\hat{x}_l(\theta), y(\theta), \Phi, B_l, b_l, w$)
        Compute $s_{l-1} = $ SSIM($\hat{x}, \hat{x}_{l-1}$)
        if $|s_l - s_{l-1}| \leq \tau$ and $b_l < B_l$ for each level $l$ then
            for $1 \leq l \leq L$ do
                $b_l = b_l \times 2$
                end for
                $w = w \times 2$
            end if
            Update $\hat{x} \leftarrow \hat{x}_l$
        until $|s_l - s_{l-1}| \leq \tau$

$x_1$ and $x_3$ are used as reference frames, while the second frame, $x_2$, is the “test frame” used to measure reconstruction performance. In all cases, the reference frame is BCS sampled with a relatively high subrate of $S_1 = 0.5$ and reconstructed using BCS-SPL [3]. On the other hand, the test frame is BCS sampled using a range of subrates, $S_2 \leq S_1$. For video-frame reconstruction, we use a block size of $B = 16$ for BCS and a DWT with 4 levels of decomposition as the sparsity basis for BCS-SPL reconstruction. Block-based sampling operator $\Phi_B$ is a $B \times B$ dense Gaussian matrix.

The reconstructed reference frames are used to create a prediction of each block of the test frame; afterward, residual reconstruction of the test frame is conducted. We investigate the Tikhonov and $\ell_1$ prediction strategies as discussed in Sec. III. For the Tikhonov approach, we use a regularization parameter of $\lambda = 0.25$. Additionally, for the $\ell_1$-regularized MH prediction, we use GPSR$^2$ [18] to find the weights. We also consider performance of the straightforward BCS-SPL reconstruction of the test frame independent of the reference frame. In all cases, a spatial window size of $\pm 15$ pixels about the current block is used as the search space for finding the hypotheses.

The PSNR performance of the test-frame reconstruction as the subrate, $S_2$, for the test frame varies is presented in Table I. As can be seen in Table I, the proposed Tikhonov-regularized MH prediction provides significantly superior reconstruction for $x_2$ at low subrates as compared to the $\ell_1$-regularized prediction of [8]. For higher subrates near $S_2 \approx 0.5$, the performance of the $\ell_1$ regularization is generally more competitive, and even exceeds that of the proposed Tikhonov regularization for the News sequence at $S_2 = 0.5$. However, such a high-subrate case is of less interest than low-subrate reconstructions due to the necessity of maintaining the subrate of non-key frames as low as possible to minimize the overall sampling rate of the system.

In terms of computation, MH prediction performs much more quickly than the $\ell_1$ method, taking just a few minutes for a single frame reconstruction, while the $\ell_1$ method can take exceedingly long to calculate, up to 4 or 5 hours for a single frame.

B. Still Images

The performance of the MH-BCS-SPL and MH-MS-BCS-SPL is evaluated on a number of grayscale images of size 512×512 (see Fig. 2) with $\tau = 0.0001$. We compare to the original BCS-SPL [3] and MS-BCS-SPL [4] as well as to the TV reconstruction described in [10] and a multiscale variant of GSPR as described in [19]. Block-based sampling operator $\Phi_B$ is a $B \times B$ dense Gaussian matrix; on the other hand, TV uses the scrambled block-Hadamard SRM of [1] to provide a fast whole-image CS sampling. The multiscale GSPR (MS-GPSR) uses the same $\Omega$ as MS-BCS-SPL in implementing GSPR reconstruction at each DWT level. We use our implementations$^3$ of BCS-SPL and MS-BCS-SPL, and $l_1$-MAGIC$^4$ for TV.

The reconstruction performance of the various algorithms under consideration is presented in Table III. In all cases except the “Barbara” and “Barbara2” images, MH-MS-BCS-SPL performs uniformly better than other algorithms. For “Barbara,” MH-BCS-SPL provides a substantial gain in reconstruction quality over TV, generally on order of a 5- to 7-dB increase in PSNR. A visual comparison of the various algorithms is shown in Fig. 3.

As can be seen in Table II, in terms of execution time, reconstruction with MH-BCS-SPL and MH-MS-BCS-SPL is, as expected, slower than BCS-SPL and MS-BCS-SPL due to the complexity of the MH prediction. Both algorithms run for less than 3 minutes on a quadcore 2.67-GHz machine. On the other hand, the execution times of TV are much slower than MH-BCS-SPL and MH-MS-BCS-SPL, with TV requiring more than 20 minutes to reconstruct a single image even with fast SRM implementation of the sampling operator.

VI. CONCLUSIONS

In this paper, we considered how the high degree of spatial correlation in images and frame-to-frame temporal correlation in video signals can be exploited to enhance CS reconstruction. In essence, we formed MH predictions using a distance-weighted Tikhonov regularization to find the best linear combination of hypotheses. The MH predictions were used to create a measurement-domain residual of the signal to be recovered—such a residual is typically more compressible than the original signal making it more amenable to CS reconstruction. The proposed approach to MH prediction showed a significant improvement in reconstruction quality over several alternative

reconstructions for both image and video reconstruction, including, for video, a straightforward intraframe reconstruction as well as an alternative $\ell_1$-regularized prediction/residual reconstruction; and, for still images, a popular TV-based reconstruction.
