The Izu-Bonin-Mariana (IBM) arc system extends 2800km from near Tokyo, Japan to Guam and is an outstanding example of an intraoceanic convergent margin (IOCM). Inputs from sub-arc crust are minimized at IOCMs and output fluxes from the Subduction Factory can be more confidently assessed than for arcs built on continental crust. The history of the IBM IOCM since subduction began about 43 Ma may be better understood than for any other convergent margin. IBM subducts the oldest seafloor on the planet and is under strong extension. The stratigraphy of the western Pacific plate being subducted beneath IBM varies simply parallel to the arc, with abundant off-ridge volcanics and volcanics in the south which diminish northward, and this seafloor is completely subducted. The Wadati-Benioff Zone varies simply along strike, from dipping gently and failing to penetrate the 660 km discontinuity in the north to plunging vertically into the deep mantle in the south. The northern IBM arc is about 22km thick, with a felsic middle crust; this middle crust is exposed in the collision zone at the northern end of the IBM IOCM. There are four Subduction Factory outputs across the IBM IOCM: (1) serpentinite mud volcanoes in the forearc, and as lavas erupted from along (2) the volcanic front of the arc and (3) back-arc basin and (4) from arc cross-chains. This contribution summarizes our present understanding of matter fed into and produced by the IBM Subduction Factory, with the intention of motivating scientific efforts to understand this outstanding example of one of earth’s most dynamic, mysterious, and important geosystems.

1. INTRODUCTION

The Izu-Bonin-Mariana arc system (IBM) stretches over 2800 km, from near Tokyo, Japan, to beyond Guam, U.S.A. (Figure 1), and is an excellent example of an intraoceanic convergent margin (IOCM). IOCMs are built on oceanic crust and contrast fundamentally with arcs built on continental crust, such as Japan or the Andes. Because IOCM crust is thinner, denser, and more refractory than that beneath Andean-type margins, study of IOCM melts and fluids allows more confident assessment of mantle-to-crust fluxes and processes than is possible for Andean-type convergent margins. Because IOCMs are far removed from continents they are less affected by the large volume of alluvial and glacial sediments. The consequent thin sedimentary cover makes it much easier to study arc infrastructure and determine the mass and composition of subducted sediments. Active hydrothermal systems found on the submarine parts of IOCMs give us a chance to study how many of earth’s important ore deposits formed.
IBM presents an outstanding opportunity to study the operation of the Subduction Factory at an IOC, for several reasons: 1) the history of IBM evolution is one of the best known of any convergent margin; 2) there are four opportunities across the arc to sample products of the Subduction Factory—the forearc, the active magmatic arc, arc cross-chains, and back-arc basins—more than any other convergent margin; 3) Subducted sediments are simple, diagnostic, and completely subducted; 4) IBM is an excellent example of convergent margins undergoing extension; and 5) IBM is large and diverse. Furthermore, a collision zone in the north provides an unparalleled opportunity to study the composition of middle IBM crust and so better infer products and processes leading to the formation of this crust. Additional information about the advantages of IBM for the Subduction Factory experiment can be found in the Subduction Factory Science Plan (http://www.ldeo.columbia.edu/margins/SF_Sci_Plan_revised.pdf).

The following overview of the IBM arc system is presented in the context of the Subduction Factory experiment. Emphasis is on the active components and on the nature of inputs and outputs. Although we try to summarize the most important points, it is important to appreciate that the Subduction Factory is one of earth's largest and most complex geosystems, planetary in scale and extending thousands of kilometers into the earth. This is certainly true for IBM. While we have a good understanding of what goes in and what comes out of the IBM Subduction Factory, we are just beginning to understand how it operates.

2. NOMENCLATURE AND GEOGRAPHY

The IBM arc system lies along the eastern margin of the Philippine Sea Plate in the Western Pacific. In this paper we will use different terms to describe all or part of the subducting Pacific Plate, including 'subducting components', 'subducted slab', and 'incoming plate', and the overriding crust and mantle, including 'mantle wedge', 'arc crust', and 'overriding plate'. Subducted and overriding materials are the two key elements of the IBM Subduction Factory. We define the Subduction Factory as that part of a convergent margin/subduction zone system where material is transferred from subducted lithosphere and sediments to the overlying mantle wedge for processing, from which some products are transferred to the surface. At one time, all of the eastern Philippine Sea Plate—from New Guinea to Japan—was an active convergent plate boundary responsible for subducting the Pacific Plate, but active-arc volcanism has ceased in the region south of the Challenger Cusp (Figure 1). Because we are concerned here only with that part of the IBM system associated with an active Subduction Factory, we focus on the IBM arc system east and north of the Challenger Cusp. We consider the width of the Subduction Factory to correspond to the active part of the IBM arc system, which lies between the trench—entry slot for all non-mantle contributions to the Subduction Factory—and a western limit that is defined by the most distant point from the trench where Subduction Factory products issue, such as lavas from back-arc spreading ridges or most distal parts of cross-chain volcanism. So defined, the IBM Subduction Factory is no more than 350 km wide. However, products of IBM generated during its Tertiary history extend as far west as the Palau-Kyushu Ridge, up to 1,000 km from the trench. We cannot define the depth limit of the IBM Subduction Factory, because we don't know at what depth transfer of material from subducted plate to overlying mantle ceases.

The northern boundary of the active IBM arc system follows the Nankai Trough northeastward and onto southern Honshu, joining up with a complex system of thrusts that continue offshore eastward to the Japan Trench. The intersection of the IBM, Japan, and Sagami trenches is the only trench-trench-trench triple junction on earth. Thus defined, the pertinent portion of the IBM arc system spans over 25° of latitude, from 11°N to 35°20'N. It is bounded on the east by a great trench, which ranges from almost 11 km deep in the Challenger Deep (deepest spot on Earth's surface) to less than 3 km where the Ogasawara Plateau enters the trench (Figures 2, 3). The Ogasawara Plateau [Smoot, 1983] separates a deeper portion of the IBM Trench to the north—where depths of 8-9 km are common—from a shallower trench in the south, characterized by depths of 6-8 km. The difference in trench depths can be reasonably ascribed to the different histories of the Pacific Plate north and south of the Ogasawara Plateau, which was built near the boundary between Jurassic seafloor to the south and Cretaceous seafloor to the north (Figure 3). The presence of a generally deeper trench to the north and shallower trench to the south contrasts with the expected greater trench depth for the older, southern seafloor [Stein and Stein, 1992]. This may reflect the fact that seafloor to the south was rejuvenated by mid- and late- Cretaceous off-ridge volcanism whereas seafloor to the north was not.

Variations in age and bathymetry on the incoming plate north and south of the Ogasawara Plateau do not correspond in any obvious way with morphological variations along the arc system, which can be reasonably divided into thirds along strike. Boundaries are defined by the Sofugan Tectonic Line (~29°30'N) separating the Izu and Bonin segments, and by the northern end of the Mariana Trough back-
are basin (−23°N), that we take to define the boundary between the Bonin and Mariana segments. Forearc, active arc, and back arc are expressed differently on either side of these boundaries (Figure 4).

The forearc is that part of the arc system between the trench and the line of arc volcanoes that define the magmatic front. The IBM forearc is very narrow in the south, between the Challenger Cusp and Guam. Elsewhere, from Guam to Honshu, it is about 200 km wide. Uplifted sectors of the forearc situated near the magmatic front are called the ‘frontal arc’ [Karig 1971b]. The frontal arc is composed of Eocene igneous basement surmounted in the south by reef terraces of Eocene and younger age. Where exposed above sealevel, the frontal arc is expressed as the island chain from Guam north to Ferdinand de Medinilla in the Marianas and as the Bonin or Ogasawara Islands farther north. There is no accretionary prism associated with the IBM forearc or trench.

The magmatic axis of the arc is well defined from Honshu to Guam (Figure 2). This ‘magmatic arc’ is often submarine, reflecting fluctuations between 1 and 4 km water depth for the platform on which the arc volcanoes are built. Volcanic islands dominate the magmatic front from Oshima south to Sofugan (the Izu Islands). The Izu segment farther south also contains several submarine felsic calderas [Yuasa and Nohara, 1992]. The Izu segment is punctuated by inter-arc rifts [Klaus et al., 1992; Taylor et al., 1991]. The Bonin segment to the south of the Sofugan Tectonic Line contains mostly submarine volcanoes and a few island volcanoes, such as Nishino-shima. The highest elevations in the IBM arc (not including Fujiyama on the Izu Peninsula, where IBM comes onshore in Japan) are found in the southern part of the Bonin segment, where the extinct volcanic islands of Minami and Kita Iwo Jima rise to almost 1000 meters above sealevel. The bathymetric high associated with magmatic arc of the Izu and Bonin segments is often referred to as the Shichito Ridge in Japanese publications, and the Bonins are often referred to as the Ogasawara Islands. Volcanoes erupting lavas of unusual composition—the shoshonitic province—are found in the transition between the Bonin and Mariana arc segments. The magmatic arc in the Marianas is submarine to the north of Uracas (Northern Seamount Province), is mostly defined by volcanic islands in the Central Island Province, and again becomes submarine south of Anatahan (Southern Seamount Province) [Bloomer et al., 1989b; Meijer, 1982].

The back-arc regions of the three segments vary markedly (Figure 4). The Izu segment is marked by several volcanic cross-chains which extend SW away from the magmatic front [Ishizuka et al., 1998]. The Bonin arc segment has no back-arc basin, inter-arc rift, or rear-arc cross chains.

Figure 1. Generalized locality map for the Izu-Bonin-Mariana Arc system. Dashed line labeled STL = Sofugan Tectonic Line. Traverse shown in Figure 2 follows the magmatic arc from Japan through the Izu, Bonin, and Mariana magmatic arcs. Locations of profiles shown in Figure 4 are shown and labeled 4A, 4B, and 4C. Location of cross-chains is shown, with Zenisu (Z) at the far north, Kan’ei (K) and Genroku (G) farther south in the Izu arc, and Kasuga (Ka) in the Marianas.
The Mariana segment is characterized by an active back arc basin [Fryer, 1995] known as the Mariana Trough. The Mariana Trough shows marked variations along strike, with seafloor spreading south of 19°15′ and rifting farther north [Gribble et al., 1998; Martinez et al., 1995].

The IBM arc system south and west of Guam is markedly different than the region to the north. The forearc region is very narrow and the intersection of backarc basin spreading axis with the arc magmatic systems is complex. Earlier ideas that this was a region dominated by dextral strike-slip faults which trend E-W are not supported by more recent geophysical data sets [Martinez et al., 2000].

3. EARLY STUDIES OF THE IBM ARC SYSTEM

Study of the IBM arc system began with geologic studies of the islands and has gone down from this. An excellent history of work in the Mariana dating back to 1792 is given by Cloud et al. [1956]. Modern geologic studies began with the identification of boninite lavas from the Ogasawara Islands by Petersen [1890]. The term ‘boninite’ was neglected for 90 years, but the rocks that Petersen described are now recognized as among the most interesting and important of all igneous rocks [Crawford et al., 1989]. Japan controlled the entire IBM arc system except Guam for 30 years, from 1914 until 1944, during which time the volcanic islands were studied [Tanakadate, 1940; Tsuya, 1936; Tsuya, 1937]. Hobbs [1923] used the Marianas as an example of how ‘asymmetric forces’ produce arcuate mountain ranges, incidentally coining the term ‘island arc’.

The Second World War raged around the Philippine Sea Plate and particularly along the IBM arc, with tens of thousands of deaths in 1944 and 1945. Soundings collected by U.S. warships led to the first overview of the marine geology of the region [Hess, 1948]. This paper showed the way for modern research on the Subduction Factory (Hess, 1948, p.422): “The trenches are the topographic expression of the dominant structural feature of the region, the downbuckling of the crust or tectogene. This structure...is the core and essence of mountain building, and all other major structures as well as the volcanic activity and the seismic activity of the region, are subordinate to and related to it.” Hess mistakenly identified a peridotite belt along the IBM islands but would have been gratified to learn that ultramafic rocks are common, both as part of the inner trench wall and as part of serpentine mud volcanoes in the forearc.
Figure 3. Simplified geologic and magnetic map of the western Pacific, modified after Nakanishi et al. [1992]. Relative motion of the Pacific Plate with respect to the Philippine Sea Plate is shown with arrows, numbers correspond to velocities (mm/year), after Seno et al. [1993].
Figure 4. Greatly simplified cross sections along the IBM arc system, showing variations in morphology and tectonic style from north (Izu) through central (Bonin) and southern (Mariana) segments. Locations are shown in Figure 1. Sections taken from various reports, especially Honza and Tamaki [1985], Hussong and Uyeda [1982] Karig [1971b], and Taylor [1992]. T= trench, solid triangle = magmatic arc. Vertical exaggeration ~ 25x.

As an historical aside, former U.S. President George H.W. Bush was shot down over the Bonin Islands in September, 1944, one small event in the bloody military campaign fought on this island arc. The IBM arc’s most important role in world history may have occurred when the U.S.A. launched atomic bomb attacks on Hiroshima and Nagasaki from Tinian in the Marianas to end the Second World War.

Geologic studies of some of the major islands occurred during the post-war period, particularly on Guam [Tracey et al., 1964], Saipan [Cloud et al., 1956], Pagan [Corwin et al., 1957] and Iwo Jima [McDonald, 1948]. Japanese scientists resumed geologic investigations in the northern IBM arc, for example with the petrologic studies of Isshiki [Isshiki, 1955; Isshiki, 1963]; as part of this effort, the greatest peacetime loss of life ever to befall the earth science or oceanographic community occurred when the submarine volcano Myojin-sho erupted on the night of Sept. 23, 1952 and sank the Kaiyo-maru, killing 31 scientists and crew [Jagger, 1952].

The plate tectonic revolution revived global scientific interest in the IBM arc. Seismological re-examination of the Wadati-Benioff Zone around the Philippine Sea plate led this effort [Katsumata and Sykes, 1969]. The principal features of crustal structure were outlined by Murachi et al. [1968], who established that IBM crust was about 20 km thick. The early- to mid-1970s was an exciting time for understanding particularly the southern IBM system, beginning with the startling discovery of active seafloor spreading behind the Mariana arc [Karig, 1971b]. This was confirmed by the first integrated geochemical and isotopic study of the IBM arc system [Hart et al., 1972], which revealed remarkable similarities between the composition of Mariana Trough ‘back-arc basin basalts’ and mid-ocean ridge basalts, and by the recognition of high heatflow in the basin [Anderson, 1975]. Karig realized that many of the deep basins of the Philippine Sea Plate and elsewhere around the margin of the Western Pacific evolved in a manner similar to that of the Mariana Trough. Karig [1971a] established a firm historical and tectonic perspective for understanding the arc system. The first modern whole-rock geochemical study of the Mariana volcanic islands [Larson et al., 1975] and the first effort to use radiogenic isotopes to identify subducted components in Mariana Arc lavas [Meijer, 1976] completed a broad geoscientific sketch of the arc system. These studies motivated the convergent margin ‘biopsy’ undertaken along 18°N by DSDP Leg 60 [Hussong and Uyeda, 1982]. About this time, the significance of the IBM collision zone began to be appreciated. Studies of the IBM arc system since the mid-1970’s have proliferated, as the IBM arc system has come to be appreciated as an outstanding place to study the operation of convergent plate margins.

4. HISTORY OF THE IBM ARC SYSTEM

The evolution of the IBM arc system is among the best known of any convergent margin. Because IBM has always been an arc system under strong extension, its components encompass a broad area, from the Palau-Kyushu Ridge to the IBM trench (Figure 1). In general, the oldest components are preserved farther west, and a complete record of
evolution is preserved in the forearc. The early history has been outlined by Bloomer et al. [1995] and Stern and Bloomer [1992], who concluded that the IBM subduction zone began as part of a hemispheric-scale foundering of old, dense lithosphere in the Western Pacific (Figure 5A). The beginning of large-scale lithospheric subidence (not true subduction, but its precursor) is constrained by the age of igneous basement of the IBM forearc, including boninites, to have begun by about 50 Ma [Bloomer et al., 1995; Cosca et al., 1998]. During this stage, the forearc was the site of igneous activity, including the eruption of deplet ed tholeiites, boninites and associated low-K rhyodacites [Hickey and Frey, 1982; Stern et al., 1991; Taylor et al., 1994]. Magmatic activity localized along the present magmatic arc and allowed forearc lithosphere to cool in Late Eocene or Early Oligocene time. This marked the transition from lithospheric subidence to subduction. True subduction—that is, the beginning of down-dip motion of the lithosphere—probably began about 43 Ma, when the Pacific Plate suddenly—and otherwise inexplicably—changed from a northerly to more westerly motion [Richards and Lithgow-Bertelloni, 1996].

This simple model of how subduction began depends in part on the orientation of spreading centers and fracture zones, needed to localize large-scale lithospheric foundering. Stern and Bloomer [1992] preferred an E-W spreading 'Tethyan' spreading regime and a N-S fracture zone in which the IBM subduction zone nucleated, but paleomagnetic data suggest that elements of the IBM arc system have rotated ~90° clockwise since the early Oligocene [Hall et al., 1995]. It is difficult to reconcile the simple model of subduction initiation via fracture zone collapse with paleo-geographic models inferred from paleomagnetic data. Large-scale rotations seemingly required by paleomagnetic data have recently been questioned because the IBM collision zone has been at about the same place for the last 13 Ma, an interval during which paleomagnetic data suggest the Philippine Sea Plate (and the collision zone) should have migrated several hundred km to the NE zone (see discussion and reply by Ali and Moss [1999] and Takahashi and Saito [1999]).

The beginning of true subduction localized the magmatic arc close to its present position, about 200 km away from the trench, and allowed the sub-forearc mantle to stabilize and cool (Figure 5B). Note that because of a lack of accretionary prism, the distance from the magmatic arc to the trench is thought not to have changed much since the magmatic arc first became established. The arc stabilized until about 30 Ma, when it began to rift to form the Parece Vela Basin. Spreading propagated north and south from this point, resulting in the 'bowed-out' appearance of the Parece Vela basin [Taylor, 1992]. Spreading began in the northernmost part of the IBM arc about 25Ma and propagated south to form the Shikoku Basin [Kobayashi et al., 1995]. These two spreading systems met about 20 Ma and spreading continued until about 15 Ma (Figure 5C). The arc was disrupted during rifting but began to build again as a distinct magmatic system once seafloor spreading began. Arc volcanism, especially explosive volcanism, waned during much of this episode, with a resurgence beginning about 20 Ma in the south and about 17 Ma in the north [Lee et al., 1995; Taylor, 1992]. Tephra from northern and southern IBM show that strong compositional differences observed for the modern arc have existed over most of the arc's history, with northern IBM being more depleted and southern IBM being relatively enriched [Bryant et al., 1999]. A similar conclusion resulted from studies of coarser volcaniclastic materials [Gill et al., 1994]. About 15 Ma, the northernmost IBM

B) Early Arc; 1st Unrifted Arc (40-30 Ma)

C) Shikoku-Parece Vela Back-Arc Basin (30-15 Ma)*

D) 2nd Unrifted Arc (15-7 Ma)*

E) Marianas Trough Back-Arc Basin (7 Ma - present)

*Collision of Northern IBM Arc with Honshu began about 15Ma

Figure 5. Simplified history of the IBM arc system. Shaded areas are magmatically inactive, cross-hatched areas are magmatically active.
began to collide with Honshu, probably as a result of new
subduction along the Nankai Trough.

A new episode of rifting to form the Mariana Trough
back-arc basin began sometime after 10 Ma, with seafloor
spreading beginning about 3-4 Ma [Bibee et al., 1980;
Yamazaki and Stern, 1997] (Figure 5D). Because the old arc
is physically removed from above the site of melting in the
mantle when a back-arc basin forms, the present Mariana
arc volcanoes cannot be older than 3-4 Ma but the Izu-
Bonin volcanoes could be as old as ~25 Ma. The Izu inter-
arc rifts began to form about 2 Ma [Taylor, 1992].

5. INPUTS INTO THE SUBDUCTION FACTORY

Everything delivered to the IBM trench, including the
entire sedimentary section, is subducted. In addition, Cloos
[1992] argued that the subduction channel shear zone
beneath the Marianas widens with depth in the shallow
parts of the subduction zone, so that subcretion is unlikely
and the entire subducted assemblage—minus perhaps a few
accreted seamounts—is delivered to and processed in the
Subduction Factory. Below we discuss the delivery vectors
for this input, modifications of the lithosphere just prior to
its descent, and the stratigraphy and composition of sedi-
ments on the Pacific plate adjacent to the trench.

5.1. Plate Motions

The IBM arc system is part of the Philippine Sea Plate, at
least to the first approximation. Although the IBM arc
deforms internally—and in fact in the south is separated
from the Philippine Sea Plate by a spreading ridge in the
Mariana Trough—it is still useful to discuss approximate
rates and directions of that plate with its lithospheric neigh-
bors, because these define how rapidly and along what
streamlines material is fed into the Subduction Factory. The
Philippine Sea Plate (PH) has four neighboring plates: the
Pacific (PA), Eurasian (EU), North America (NA), and
Caroline (CR). There is minor relative motion between PH
and CR; furthermore, CR does not feed the IBM
Subduction Factory, so it is not discussed further. The North
America plate includes northern Japan, but relative motion
between it and Eurasia is sufficiently small that relative
motion between PH and EU explains the motion of interest.
The Euler pole for PH-PA as inferred from the NUVEL-1A
model for current plate motions [DeMets et al., 1994] lies
about 8°N, 137.3°E, near the southern end of the Philippine
Sea Plate. PA rotates around this pole CCW ~1°/Ma with
respect to PH. The PH-PA Euler pole inferred from earth-
quake slip vectors lies very close to the NUVEL-1A pole
[Seno et al., 1993]. This means that relative to the south-
ermost IBM, PA is moving NW at about 20-30 mm/yr,
whereas relative to the northernmost IBM, PA is moving
WNW and twice as fast (Figure 3).

The NUVEL-1A Euler Pole for EU-PH lies about 51°N,
160.5°E, off the coast of Kamchatka. Earthquake slip vec-
tors [Seno et al., 1993] indicate a more southerly pole location,
NE of Hokkaido. Recent GPS (global positioning
satellite) campaigns [Kotake et al., 1998] indicate that the
EU-PH Euler Pole lies ~42°N, 152.5°E, a bit south of
Seno’s slip vector pole, with a CW rotation of 1.5°/Ma for
PH relative to EU. PH is moving NW at about 40 mm/year
relative to Hokkaido, so velocities increase to the south
along the EU-PH plate boundary. To a first approximation,
the GPS, NUVEL-1A, and earthquake slip vector data
agree, except for Guam, which GPS data indicate is moving
much more slowly to the NW (~10 mm/year) than predicted
from NUVEL-1A. This is due to the opening of the Mariana
Trough, for which full spreading rates of 3-5 cm/year are
inferred [Bibee et al., 1980; Hussong and Uyeda, 1982;
Yamazaki and Stern, 1997].

It should be noted that the IBM arc is not experiencing
trench ‘roll-back’, that is, the migration of the trench towards
the ocean. The trench is moving towards Eurasia, although a
strongly extensional regime is maintained in the IBM arc sys-
tem because of rapid PH-EU convergence. The nearly verti-
cal orientation of the subducted plate beneath southern IBM
exerts a strong “sea-anchor” force that strongly resists its lat-
eral motion. Back-arc basin spreading is thought to be due to
the combined effects of the sea-anchor force and rapid PH-
EU convergence [Scholz and Campos, 1995].

The obliquity of convergence between PA and the IBM
arc system change markedly along the IBM arc system.
Figure 6 shows the plate convergence inferred from earth-
quake slip vectors [McCaffrey, 1996]. This is nearly
strike-slip in the northernmost Marianas, adjacent to and
south of the northern terminus of the Mariana Trough,
where the arc has been ‘bowed-out’ by back-arc basin
opening, resulting in a trench which strikes approximately
parallel to the convergence vectors. Convergence is
strongly oblique for most of the Mariana Arc system but is
more nearly orthogonal for the southernmost Marianas
and most of the Izu-Bonin segments. Figure 6 also shows
the arc-parallel slip rate in the forearc, which reaches a
maximum of 30mm/yr in the northern Marianas.
According to McCaffrey, this is fast enough to have pro-
duced geologically significant effects, such as unroofing
of high-grade metamorphic rocks, and provides one expla-
nation for why the forearc in southern IBM is tectonically
more active than that in northern IBM.
5.2. Trench and Forearc Bulge

The trench and the associated forearc bulge mark where raw materials are fed into the Subduction Factory and where the lithosphere is first bent or broken to begin its downward trajectory. The phenomenon of the trench is well known and will not be further discussed, other than to note that the IBM trench lacks sediment fill [Bellaiche, 1980]. Flexure of lithosphere about to enter a subduction zone is commonly observed just outboard of the trench, where it is referred to as the “outer rise”. The flexural bulge rises to about 300m above the surrounding seafloor just before the trench, and this flexure can be used to constrain the state of stress across the convergent margin. Based on application of an elastic-plastic model, Bodine and Waits [1979] concluded that horizontal stresses are low across the northern Mariana Trench, intermediate across the southern Mariana and Bonin trench segments, and high across the Izu trench segment. Vertical stress was modeled by Harry and Ferguson [1991], who noted larger vertical stresses for the southern Marianas than the southern Izu segment. Harry and Ferguson [1991] also concluded that the load inducing flexure results from a narrow zone of interplate coupling located 15-20 km arcward of the trench axis, and that the weight of the subducted slab does not contribute to the support of the trench-outer rise bathymetry. Faulting associated with development of the flexural bulge provides one last opportunity for fluids to be introduced deep into the about-to-be subducted plate. These occur as ‘stair-stepping’ normal faults which trend parallel to the trench [Bellaiche, 1980]. Open cracks or tension fractures showing no displacement are associated with the normal faults [Ogawa et al., 1997]. These fractures are thought to allow seawater to penetrate deeply into mantle lithosphere, forming serpentinites that carry substantial water into the Subduction Factory [Peacock, 2001].

5.3. Geology and Composition of the Westernmost Pacific Plate

The IBM arc system now subducts mid-Jurassic to Early Cretaceous lithosphere, with younger lithosphere in the north and older lithosphere in the south. It is not possible to directly know the composition of subducted materials presently being processed by the IBM Subduction Factory—what is now 130 km deep in the subduction zone entered the trench 4-10 million years ago. However, the composition of the Western Pacific seafloor—sediments, crust, and mantle lithosphere—varies sufficiently systematically that, to a first approximation, we can understand what is now being processed by studying what now lies on the seafloor east of the IBM trench.

The seafloor east of the IBM arc system can be subdivided into a northern ‘smooth’ portion and a southern ‘rough’ portion, separated by the Ogasawara Plateau (Figure 3). These large-scale variations mark distinct geologic histories to the north and south. The featureless north is dominated by the Nadezhd Basin. In the south, crustal alignments of seamounts, atolls, and islands allows define three great, WNW-SEE trending chains to be identified [Winterer et al., 1993]. The Marcus-Wake-Ogasawara Plateau extends westward from the Mid-Pacific Mountains for 3,000 km, culminating at the trench as the great Ogasawara Plateau. A second ridge intersects the trench about 20°N, and is known as the Magellan Chain. The Magellan chain is complex, with the Dutton Ridge in the north and the Magellan seamounts in the south. The southernmost ridge is the Caroline Islands Ridge, which intersects the Yap trench to the south of the Marianas, at about 9°N, and includes the only high volcanic islands on the NW Pacific plate—the islands of Truk, Ponape, and Kosrae. The first two chains formed by off-ridge volcanism during Cretaceous time, whereas the Caroline Islands chain formed over the past 20 million years. Last 20 million years by the westward passage of the Pacific Plate over a mantle hot-spot. The Marcus-Wake and Magellan chains are typified by flat-topped guyots, with summit depths on the order of 2000 m, whereas the Caroline Islands chains are much shallower. Between these chains lie two important abyssal plains or basins: the Pigafetta Basin lies between the Marcus-Wake and Magellan chains, and the East Mariana Basin lies between
the Magellan and Caroline chains. The East Mariana Basin is a flat-floored basin, with a maximum water depth of 6.1 km [Whitman, 1986], and the deepest part of the Pigafetta Basin is only slightly shallower.

The age of Western Pacific seafloor has been interpreted from magnetic anomalies [Nakanishi et al., 1992] and confirmed by drilling. Three major sets of magnetic anomalies have been identified in the area of interest [Larson and Chase, 1972]. Each of these lineation sets comprises M-series anomalies (mid-Jurassic to mid-Cretaceous) that are essentially Pacific Plate growth rings. These anomaly sets indicate that the small, roughly triangular Pacific plate grew by spreading along three ridges [Bartolini and Larson, 2001]. The oldest identifiable lineations are M33 to M35 [Nakanishi, 1993] or perhaps even M38 [Handschumacher et al., 1988]. It is difficult to say how old these lineations and the older crust might be; the oldest magnetic lineations for which ages have been assigned are M29 (157 Ma; [Channell et al., 1995]). Magnetic lineations as old as M29 are not known from other oceans, and the area in the Western Pacific that lies inside the M29 lineation—that is, crust older than M29—is on the order of 3 \times 10^6 km^2, about a third of the size of the United States. ODP site 801 lies on crust considerably older than M29 and the MORB basement there yields Ar-Ar ages of 167\pm5 Ma [Pringle, 1992]. The oldest sediments at site 801C are Callovian or latest Bathonian (~162 Ma [Harrand et al., 1990]).

Seafloor spreading in the Pacific during the Cretaceous evolved from a more E-W ‘Tethyan’ orientation to the modern N-S trend. This occurred during mid-Cretaceous time, a \sim 35-40 Ma interval characterized by a lack of magnetic reversals known as the Cretaceous Superchron. Subsequently, the location of N-S trending spreading ridges relative to the Pacific Basin migrated progressively to the east throughout Cretaceous and Tertiary time, resulting in the present marked asymmetry of the Pacific, with very young seafloor in the Eastern Pacific and very old seafloor in the Western Pacific.

Sediments being delivered to the IBM trench are about 500m thick (Figure 7). Away from seamounts, the pelagic sequence is dominated by chert and pelagic clay, with little carbonate. Carbonates are important near guyots, common in the southern part of the region. Interestingly, Cenozoic sediments are unimportant except for deposits of volcanic ash adjacent to Japan and carbonate associated with the relatively shallow Caroline Ridge and plate. Strong seafloor currents are probably responsible for this erosion or non-deposition. The compositions of sediments being subducted beneath the northern and southern parts of the IBM arc are significantly different, because of the Cretaceous off-ridge volcanic succession in the south that is missing in the north.

![Figure 7](http://www.odp.tamu.edu/publications/185_IR/VOLUME/CHAPTERS/IR185_04.PDF)

Lavas and volcanioclastics associated with an intense episode of intraplate volcanism correspond in time closely to the Cretaceous Superchron. Off-ridge volcanism became increasingly important approaching the Ontong-Java Plateau. There are 100-400m thick tholeiitic sills in the East Mariana Basin and Pigafetta Basin [Abrams et al., 1993], and at least 650m of tholeiitic flows and sills in the Nauru
Basin, near ODP Site 462 [Shipley et al., 1993]. Castillo et al. [1994] suggest that this province may reflect the formation of a mid-Cretaceous spreading system in the Nauru and East Mariana basins. Farther north, deposits related to this episode consist of thick sequences of Aptian-Albian volcaniclastic turbidites shed from emerging volcanic islands, such as preserved at DSDP sites 585 and ODP sites 800 and 801. A few hundred meters of volcaniclastic deposits probably characterizes the sedimentary succession in and around the East Mariana and Piafetta basins. Farther north still, at DSDP sites 196 and 307 and ODP site 1149, there is little evidence of mid-Cretaceous volcanic activity. It appears that the Aptian-Albian volcanic episode was largely restricted to the region south of present 20°N latitude. Paleomagnetic and plate kinematic considerations place this extensive region of off-ridge volcanism in the present vicinity of Polynesia, a broad region of off-ridge volcanism, shallow bathymetry, and thin lithosphere known as the 'Superswell' [McNutt et al., 1990; Menard, 1984].

The compositions of sediments being subducted beneath the IBM are likely to be complicated by many factors, including those related to the formation of the IBM and the evolution of the Pacific plate. In particular, the IBM is characterized by a wide range of rock types, including volcanic and sedimentary deposits, which may have different isotopic compositions. The IBM is also known to have undergone significant tectonic activity, which may have influenced the isotopic composition of the sediments.

Figure 8. Chemical composition of sediments being fed into the IBM Subduction Factory. Composites for sediments outboard of Izu-Bonin (dotted line) and Mariana (solid line) are after Plank and Langmuir [1998], (A) normalized to abundances in MORB [Hofmann, 1988] and (B) normalized to Global Subducting Sediments (GLOSS; [Plank and Langmuir, 1998]).

Wide range (Figure 9C,D). IBM arc lavas most resemble subducted volcanics on a Sr-Nd isotopic diagram but are more similar to sediment compositions on Pb isotopic diagrams.

About 470m of oceanic crust was penetrated at 801C during Legs 129 and 185 of the Ocean Drilling Program (Figure 6). These are typical MORB that were affected by low-temperature hydrothermal alteration. The isotopic compositions of Sr, Nd and Pb are also typical of Pacific MORB (Figure 9, [Castillo et al., 1992]). This crust is overlain by a 3m thick, bright yellow hydrothermal deposit [Alt et al., 1992] and about 60 m of alkali olivine basalt, 157.4±0.5 Ma old [Pringle, 1992], enriched in light REE and other incompatible elements.

6. GEOPHYSICS OF THE SUBDUCTED SLAB AND MANTLE

The deep structure of the IBM system has been imaged using a variety of geophysical techniques. This section provides an overview of these data, including a discussion of mantle structure at depths (>200 km) below the typical definition of the Subduction Factory. Although deep structure may not seem to directly influence shallow subduction processes, deep mantle features exert important controls on features coupled to the shallow subduction factory, such as slab descent, slab rheology, mantle circulation, and trench migration.
Figure 9. Isotopic composition of sediments and volcanics being fed into the IBM Subduction Factory. A) O-Sr isotopic systematics for sediments (data from Stern and Ito [1983], Woodhead and Fraser [1985], and Woodhead [1989]). B) Sr-Nd isotopic systematics for W. Pacific sediments (data from Lin [1992], Stern and Ito [1983], and Woodhead [1989] and means calculated for Jurassic seafloor and Jurassic alkali basalt at ODP 801C [Castillo et al., 1992]; alkalic sills at ODP 800 [Castillo et al., 1992]; Cretaceous off-ridge tholeiites at ODP 802 [Castillo et al., 1994], Nauru Basin (ODP 462; Castillo et al., 1991), and the Ontong Java Plateau [Mahoney and Spencer, 1991]; Magellan seamounts (Himu, Hemler, Golden Dragon); Wake seamounts (Wilde, Miami, Lamont, and Scripps) [Stanigel et al., 1991]; Marshall Islands [Davis et al., 1989]; and Caroline Islands [Hart, 1988]. Notice that data for lavas clusters about εNd ~6 to +8, 87Sr/86Sr ~ 0.727-0.740 except for the Jurassic MORB at 801C and Himu and Wilde seamounts. Approximate locations of mantle reservoirs EMI, EMII, and HIMU are also shown. Sediment samples with 87Sr/86Sr < 0.706 contain a high proportion of volcanioclastic material. Location of weighted mean for sediment being subducted beneath IBM [Plank and Langmair, 1998] is shown, along with fields for fresh MORB and IBM arc lavas. C) 207Pb/204Pb vs. 206Pb/204Pb for W. Pacific sediments and volcanics, data sources as above. D) 207Pb/204Pb vs. 206Pb/204Pb. Also shown is the estimated composition of IBM mean sediment from Plank and Langmair [1998] and the Northern Hemisphere Reference Line (NHRL) after Hart [1984]. Dashed rectangles in B-D show the areas plotted in Figure 21.
6.1. Seismicity

Spatial patterns of seismicity are essential for locating and understanding the morphology and rheology of subducting slabs, and this is particularly true for the IBM Wadati-Benioff Zone. Pioneering efforts [Katsumata and Sykes, 1969] outlined the most important features of the IBM Wadati-Benioff Zone. Their study detected a zone of deep earthquakes beneath the southern Marianas and provided some of the first constraints on the deep, vertical nature of subducting Pacific lithosphere beneath southern IBM. They also found a region of reduced shallow seismicity (≤70 km) and a lack of deep (≥300 km) events beneath the Volcano Islands adjacent to the junction of the Izu-Bonin and Mariana trenches, where the trench is nearly parallel to the convergence vector.

More recently, Engdahl et al. [1998] provided an earthquake catalog containing improved locations (Figure 10). This data set shows that, beneath northern IBM, the dip of the Wadati-Benioff Zone steepens smoothly from ~40° to ~80° southwards, and seismicity diminishes between depths of ~150 km and ~300 km (Figures 11a-c). The subducted slab beneath central IBM (near 25°N; Figure 11c) is delineated by reduced seismic activity that nevertheless defines a more vertical orientation that persists southward (Figures 11d-f).

Deep earthquakes, here defined as seismic events ≥300 km deep, are common beneath parts of the IBM arc system (Figures 10, 11). Deep events in the IBM system are less frequent than for most other subduction zones with deep seismicity, such as Tonga/Fiji/Kermadec and South America. Beneath northern IBM, deep seismicity extends southward to ~27.5°N, and a small pocket of events between 275 km and 325 km depth exists at ~22°N. There is narrow band of deep earthquakes beneath southern IBM between ~21°N and ~17°N, but south of this there are extremely few deep events. Although early studies assumed that seismicity demarcated the upper boundary of the slab, more recent evidence has shown that many of these earthquakes occur within the slab. For instance, a study by Nakamura et al. [1998] showed that a region of events beneath northernmost IBM region occur ~20 km beneath the top of the subducting plate. They propose that transformational faulting, which occurs when metastable olivine changes to a more compact spinel structure, produces this zone of seismicity. Indeed, the faulting mechanism for deep earthquakes is a hotly debated topic (e.g., [Green and Houston, 1995]), and has yet to be resolved.

Double seismic zones have been detected in the IBM subduction zone, but their significance is not understood. Beneath southern IBM, Samowitz and Forsyth [1981] found a double seismic zone at 80 to 120 km depth, with the two

zones separated by 30-35 km. Earthquake focal mechanisms indicate that the more seismic upper zone is in downdip compression, while the lower zone is in downdip extension. This double seismic zone is located at a depth where the curvature of slab is greatest; at greater depths it unbends into a more planar donfiguration. Samowitz and

Figure 10. Map view of bathymetry and seismicity in the Izu-Bonin-Mariana Subduction Factory using the earthquake catalog of Engdahl et al. [1998]. Circles denote epicentral locations; lighter circles represent shallower events, darker circles represent deeper events. Black lines denote cross-sectional areas depicted in Figure 11. Large variations in the seismic structure of the region are evident.
Figure 11. Cross-sectional views of the IBM system using the earthquake catalog of Engdahl et al. [1998]. Black circles represent hypocentral locations in volume ~60 km to each side of the lines shown in Figure 10. Large variations in slab dip and maximum depth of seismicity are apparent. Distance along each section is measured from the magmatic arc. A) Northern Izu-Bonin region. Slab dip is ~45°; seismicity tapers off from ~175 km to ~300 km but increases around 400 km, and terminates at ~475 km. B) Central Izu-Bonin region. Slab dip is nearly vertical; seismicity tapers off from ~100 km to ~325 km but increases in rate and extends horizontally around 500 km, and terminates at ~550 km. C) Southern Izu-Bonin region. Slab dip is ~50°; seismicity is continuous to ~200 km, but a very few anomalous events are evident down to ~600 km. D) Northern Mariana region. Slab dip is ~60°; seismicity is continuous to ~375 km and terminates at ~400 km, but a very few anomalous events are evident down to ~600 km. E) Central Mariana region. Slab dip is vertical; seismicity tapers off slightly between ~275 km and ~575 km, but is essentially continuous. A pocket of deep events around 600 km exists, as well as 1 deep event at 680 km. F) Southern Mariana region. Slab dip is ~55°; seismicity is continuous to ~225 km, with an anomalous event at 375 km.
Forsyth [1981] suggested that unbending or thermal stresses in the upper 150 km of the slab may cause the seismicity. For northern IBM, Iida and Furukawa [1994] detected a double seismic zone between depths of 300 km and 400 km, which also is separated by 30-35 km between the upper and lower zones. They concluded that the double seismic zone results from transformational faulting of a metastable olivine wedge in the slab. Recent work suggests that compositional variations in the subducting slab may also contribute to double seismic zones [Abers, 1996], or that double seismic zones represent the locus of serpentine dehydration in the slab [Peacock, 2001].

6.2. Seismic Anisotropy and Mantle Flow

For nearly two decades, seismic anisotropy in the form of shear wave splitting has been used to examine deformation in subduction zones [Ando et al., 1983; Fouch and Fischer, 1996; Peyton et al., 2001]. Two principal goals of mapping seismic anisotropy are a) to determine the history of strain and deformation in the mantle, and b) to evaluate coupling between lithosphere and asthenosphere. The distribution of seismicity in most subduction zones provides an ideal opportunity to examine the lateral and depth distribution of subducting and overriding plate fabric, mantle flow, and possible slab-mantle coupling.

Evaluation of shear wave splitting in phases such as S and SKS are routinely performed for most regions using standard data analysis techniques [Silver and Chan, 1991]. These measurements produce two independent pieces of information: the azimuth of propagation of the faster wave (the fast direction) and the delay between the fast and slow phases (the splitting time). The primary assumption is that olivine, the principal component of the upper mantle, is responsible for the splitting, and that the fast direction (a-axis of olivine) is aligned with either the flow direction or the direction of maximum extension [Ribe, 1989; Zhang and Karato, 1995] in the upper 200-400 km of the mantle, where dislocation creep is the dominant deformation mechanism. The magnitude of the splitting time reflects how completely olivines are aligned and how thick is the layer of aligned olivines.

Studies of seismic anisotropy near the IBM system have allowed workers to examine the distribution of strain in the mantle wedge and the subducting slab. Fouch and Fischer [1996] evaluated shear wave splitting in the northern IBM subduction zone and found fast directions of NW-SE to WNW-ENE (i.e., roughly convergence-parallel) and splitting times of ~0.5 s. These splitting values for local events are comparable to observations for most convergent margins. The geometry of ray paths did not allow them to determine the relative anisotropy of the slab, mantle wedge, and overriding plate; however, most of the ray paths sample mantle wedge structure. Modeling of the splitting data indicated that anisotropy may exist to depths no greater than ~410 km. These results indicate a relatively small strength of anisotropy, and are consistent with a model in which induced flow in the back-arc wedge is the primary cause of anisotropy beneath Izu-Bonin (Figure 12).

Xie [1992] and Fouch and Fischer [1998] examined mantle anisotropy in the southern IBM subduction zone. Using short-period waveforms and a qualitative analysis technique, Xie [1992] determined E-W fast directions and splitting times of ≤0.35 s beneath Guam. Fouch and Fischer [1998] utilized broadband waveforms and a more accurate method of waveform analysis, and found ~NW-SE fast directions and splitting times ranging from 0.1 s to 0.4 s. The steep dip of the Marianas slab makes it difficult to distinguish anisotropy in the slab from that in the mantle wedge, but the use of broadband data facilitated the analysis of frequency dependence in fast directions. Modeling of these data suggested that a combination of fossil anisotropy in the subducting slab, slab-induced flow in the mantle wedge, and anisotropy possibly due to back-arc extension in the overriding plate contribute to the shear wave splitting (Figure 12).

6.3. Slab Morphology and Lower Mantle Penetration

Although first-order slab characteristics can be constrained using earthquake locations (section 6.1), more detailed information regarding lateral and vertical variations in slab morphology is required for a complete analysis of the Subduction Factory. Additionally, the depth to which subducting slabs penetrate is fundamental for determining the nature of mantle convection in the earth, as it helps constrain details of mass and heat exchange between the upper and lower mantle [Silver et al., 1988; Anderson, 1989]. Using a variety of analysis techniques, several studies have focused on the IBM system as an end-member example of the large variations in deep seismic structure found worldwide. Most of these studies conclude that the slab beneath northern IBM stagnates near the upper-lower mantle boundary (~660 km depth; Figure 12). In contrast, the slab beneath southern and central IBM descends steeply through the upper mantle, and appears to penetrate into the lower mantle.

Residual sphere images of the southern IBM subduction zone provided some of the first conclusive evidence of slab penetration into the lower mantle [Creager and Jordan, 1986]. These images showed that the slab beneath southern IBM penetrates to depths of 900-1000 km, which can be
Figure 12. Cartoon representation of seismic observations in the IBM system. Black circles show representative seismicity for each region. Thick dashed lines show rough interpretation of tomographic images for each area. A) Northern IBM (near section A in Figure 11). Slab dip is variable, but averages around 50°. Tomographic images suggest that the slab does not penetrate the lower mantle, but extends horizontally to the west. The 410 km seismic discontinuity (thin line at 410) appears to be locally elevated; the 660 km seismic discontinuity (thin line at 660) appears to be depressed for an extended distance to the west. Seismic anisotropy indicates the presence of fabric in the mantle wedge, as well as possibly in the overriding plate and subducting slab. B) Southern IBM (near section E in Figure 11). Slab dip is slightly variable, but generally becomes vertical. Tomographic images suggest that the slab penetrates the lower mantle. Regional variations of upper mantle discontinuities have not yet been documented, but a locally elevated “410” and a locally depressed “660” (thin dashed lines) might be expected. Seismic anisotropy indicates the presence of fabric in the mantle wedge and subducting slab, as well as possibly in the overriding plate.

explained solely by thermal effects [Fischer et al., 1988]. Waveform modeling [Brudzinski et al., 1997] indicates that a horizontal high-velocity feature near 660 km depth exists beneath the northern IBM arc, consistent with the hypothesis that cold, seismically fast slab material rests on top of the upper-lower mantle boundary here. Castle and Creager [1999] used a migration method to detect scatterers at ~1000 km depth beneath the central IBM arc, which they interpreted to be produced by subducted crust.

In the past decade, high-resolution images resulting from travel-time tomography have shown that the deep subducting slab beneath northern and southern IBM behaves differently. The first of these images was produced by Van der Hilst et al. [1991], who showed that the slab beneath northern IBM deflects at the upper-lower mantle boundary near 660 km, while the slab beneath southern IBM descends through the boundary into the lower mantle (Figure 12). These results have been confirmed by Fukao et al. [1992] using slightly different data analysis and inversion techniques. Van der Hilst and Seno [1993] suggested that whether or not the slab penetrates the 660 km discontinuity may be due to the rate of trench migration: the Izu-Bonin trench appears to have migrated northwestward, while the Mariana trench appears to have remained stationary. In addition, Widiyantoro et al. [1999] used P- and S-wave data to show that the rigidity of the subducting slab beneath southern IBM is highly variable. Bulk-sound (a combination of P- and S-wave velocity) images beneath northern IBM show a clear spreading of fast-velocity material along the upper-lower mantle discontinuity, while the shear-wave images do not reveal such a layer. In contrast, both bulk-sound and shear-wave images of the southern IBM region clearly show that fast-velocity material penetrates into the lower mantle. The tomography results of Widiyantoro et al. [1999] for northern IBM are somewhat surprising given the implications of recent work by Takenaka et al. [1999], which suggest that shear-wave anomalies due to temperature variations should be more easily detected than bulk sound anomalies. However, Widiyantoro et al. [1999] suggest that rheological variations within slabs may help determine whether or not these are able to penetrate the 660-km discontinuity, and that temperature and compositional variations may not be the only explanation for the seismic results.

6.4. Upper Mantle Structure

Analysis of seismic discontinuities in the mantle transition zone between depths 410 km and 660 km (hereafter referred to as the “410” and the “660”) provide important constraints on the thermal, chemical, and rheological prop-
erties of subducting slabs. Additionally, constraints on the depth of the “660” help resolve the extent of slab penetration into the lower mantle. In general, these discontinuities are believed to be due to mineralogical phase changes in olivine due to variations in pressure and temperature. The 410 discontinuity marks the exothermic olivine—β-spinel (wadsleyite) transformation and the 660 km discontinuity marks the endothermic γ-spinel (ringwoodite)—perovskite + magnesiowüstite structural transformation [Lay, 1994]. Several studies have shown that near subduction zones, upper mantle discontinuities are generally anticorrelated, with relatively shallower “410” and deeper “660”. These observations suggest that thermal anomalies due to subducting slab material are responsible for topography on the upper mantle discontinuities.

Studies of the transition zone beneath the IBM system corroborate the tomographic and other seismic results discussed in section 6.3. In general, global studies exhibit a thickened transition zone and/or a depressed “660” near the IBM system [Flanagan and Shearer, 1998; Gu et al., 1998; Revenaugh and Jordan, 1991; Shearer and Masters, 1992; Vidale and Benz, 1992], consistent with a slab-induced thermal anomaly. Detailed studies targeting the northern IBM region have yielded results similar to the global studies. Collier and Helfrich [1997] utilized data from several seismic networks to show that the transition zone in this region may be thickened by as much as 100 km, corroborating the results of Revenaugh and Jordan [1991] and Shearer [1993]. Work by Castle and Creager [1998] showed that the “660” beneath northern IBM mimics the high-resolution tomographic results. The discontinuity is depressed westward from the trench, again suggesting that the slab lies flat on the upper-lower mantle boundary. Beneath central IBM the depressed portion of the “660” is narrow, again suggesting penetration of slab material into the lower mantle. Other studies focusing on the “660”—beneath northern IBM have shown similar depressions of the discontinuity, between 30 km and 80 km [Tajima and Grand, 1998; Wicks and Richards, 1993], but these studies do not possess the lateral resolution to illuminate details of slab penetration into the lower mantle.

7. IBM SUBDUCTION FACTORY OUTPUTS

Outputs from the Subduction Factory are found as low-temperature fluids released in the forearc and as melts erupted and emplaced along the magmatic front of the arc, in arc cross-chain volcanoes, and in back-arc basin rifts and spreading centers. These outputs define the width of the IBM Subduction Factory, which reaches a maximum of ~300 km at 18°N. In the following sections, we focus on the outputs of the IBM Subduction Factory. We first present what we know about the crustal structure of the IBM arc system, then focus on fluid outputs from the forearc before describing melts from along the magmatic front, cross-chain volcanoes, and back-arc basin rifts and spreading systems.

7.1. IBM Crustal Structure

In 1992, Japanese scientists performed an ambitious wide-angle OBS experiment at 32°15'N [Suyehiro et al., 1996; Takahashi et al., 1998](Figure 13A). This defined a relatively thin (~20 km) arc crust, that may be simplistically viewed as composed of four layers of approximately equal thickness. The upper layer with Vp=1.5-5.8 km/s represents sediments and volcanics and overlies a middle-crustal layer with Vp=6.2±0.2 km/s. The lower crust has an upper half with Vp=6.6-7.2 km/s (presumably mafic plutonics) overlying a layer with Vp=7.3±0.1 km/s. The 6.2 km/s and the 7.3 km/s layers have excited most comment because layers of these velocities are not prominent in seismic data from other intraoceanic arcs.

The presence of the 6.2 km/s layer is exciting because this velocity corresponds to a wide range of intermediate-composition plutonic rocks and is close to the mean velocity of the continental crust (6.4 km/s) [Christensen and Mooney, 1995], thereby suggesting that continental crust can be directly created in an IOC. Insight into the lithology of the IBM middle crust is provided by exposures in the Izu Collision Zone (Section 7.6). Dredges from fault scarps bounding the rifted eastern edge of the Palau-Kyushu Ridge (Figure 1) (arc crust rifted from the IBM by formation of the Shikoku and Parece-Vela basins) at 30°N also reveal extensive submarine exposures of tonalite [Taira et al., 1998]. Similar silicic rocks were dredged by P. Fryer (pers. comm., 2000) from major fault scarps in the Mariana forearc southeast of Guam. Given these exposures, Taira et al. [1998] interpret the 6.0-6.4 km/sec layer to be tonalitic. A similar 6 km/sec layer was also found in the IBM arc near 31°30'N & 33°N by Hino [1991] and in the northern Palau-Kyushu Ridge, suggesting its regional presence in at least the northern part of IBM system [Taira et al., 1998].

Velocities > 7.2 km/s, at < 20 km depth in an active arc where velocities are reduced by the high lower-crustal temperatures, are best interpreted as due to mafic granulites, pyroxenites or dunites [Christensen and Mooney, 1995], or some mixture of mafic and ultramafic cumulates as exposed in the roots of some arc complexes [Burns, 1995]. In the forearc, these same velocities may correspond to variably-serpentinized upper mantle.

Although Suyehiro et al. [1996] provide the best cross-section yet of IBM arc crust, important geologic differences
Izu-Bonin (Ogasawara), 32° N

Mariana arc, 15° N (Tinian)

Central Aleutians, 172.5° W

Figure 13. Arc-perpendicular cross-sections aligned along the volcanic front, redrawn to a uniform vertical exaggeration (x2) and scale, and with uniform velocity shading. "6.2" and "7.3" identify the 6.2±0.2 km/s middle crustal layer and 7.3±0.1 km/s deepest crustal layer of the IBM arc. Neither layer is prominent in the other two models. Redrawn after A: [Suyehiro et al., 1996]; B: [Lange, 1992]; C: [Holbrook et al., 1999].

along strike make it questionable whether this structure can be extrapolated to the crust of southern IBM. A German OBS study across the Mariana arc-backarc at 15°N [Lange, 1992] provides a crude velocity model and a crustal thickness of only 16 km (Figure 13b). It is intriguing that neither the 6.2 km/sec nor the 7.3 km/sec layers seen at 32°15'N were detected beneath the Marianas. This section broadly agrees with earlier sonobuoy measurements at 18°N [LaTrace and Hussong, 1980] but gravity data have been used to infer a 220-km thick crust [Sager, 1980]. This leaves open the question of whether a deeper mafic layer might be present but not recognized because of limited pen-
etration of these seismic experiments. Recognizing high-
velocity lower-crustal layers is a particular problem for
older surveys in which only first-arrival times were mod-
eled [Hyndman and Klemperer, 1989]. Even in modern sur-
evies, the lower-crustal velocity and thickness of such layers
can be hard to constrain tightly [Sayehiro et al., 1996;
Takahashi et al., 1998]. However, comparison with the
Aleutians, the only other arc for which such high-quality
data exist [Fledner and Klemperer, 1999, 2000; Holbrook
et al., 1999](Figure 13C) suggests that very fast (7.3 km/sec)
layers are not ubiquitous beneath arcs. Layers with
similar velocities are known from the lower crust of rift
provinces [Christensen and Mooney, 1995] and it is possi-
ble that the high velocities observed for the IBM lower crust
represent mafic/ultramafic underplating related to the active
rifting in the Izu-Bonin segment of the arc [Klaus et al.,
1992], rather than to arc magmatism. Layers in the upper
and middle crust are easier to recognize than those in the
lower crust, so it seems very likely that, if a similar 5-km-
thick 6.2 km/s layer was present, it would have been detec-
ted by the seismic experiments in all three regions (Figure
13), suggesting that this layer in particular may be restrict-
et to the northern part of the IBM chain.

The crustal structure of the IBM arc at 32°15′N is well
enough known that Taira et al. [1998] were able to calcu-
late a mean crustal composition of 56% SiO2, and a mean
crustal growth rate of 80 km3/km/Ma. This calculation
required interpreting which parts of the seismically-defined
arc crust are pre-existing oceanic crust, or back-arc basin
crust, or (in the forearc) hydrated mantle. As discussed pre-
viously, important uncertainties remain in extrapolating
these results along the full length of the IBM system. Until
a new generation of multiscale seismic experiments is
undertaken, we can only approximate the composition and
volume of the arc.

The Mariana Trough back-arc basin has a crustal struc-
ture that is similar to normal oceanic crust. Three inde-
pendent efforts in the late 1970s used seismic refraction to
examine the structure of Mariana Trough crust at 18°N.
Bibee et al. [1980] examined crustal structure within 50 km
of the ridge, in the region underlain by new oceanic crust.
Another study [LaTraille and Hussong, 1980] examined
regional crustal structure, from the W. Mariana Ridge
across the Mariana Trench and eastward onto the Pacific
Plate. The first study concluded that the crust was 5 to 7 km
thick, with a velocity structure typical of other slow-spreading
ridges. Seismically slow mantle was not found beneath
the spreading axis. In contrast, the study of LaTraille and
Hussong [1980] only imaged the Moho in the western part
of the Mariana Trough, more than 80 km away from the
spreading axis and beneath the region underlain by rifted
arc crust. They concluded that the crust was about 6 km
thick in the westernmost Trough and thinned towards the
spreading axis. They also noted that the crust was extreme-
ly heterogeneous and that it was associated with low-veloc-
ity upper layers similar to those found on very young crust
of other slow-spreading ridges. These two results are thus
somewhat contradictory.

The third refraction study focused on the structure of the
Pagan Fracture Zone, near 18°N. This study used 6 ocean-
bottom seismometers to generate two orthogonal refraction
crustal profiles, with one line parallel and one normal to the
ridge axis [Sinton and Hussong, 1983]. They found that
the crust along the spreading ridge away from the fracture zone
is between 4 and 6 km thick, while the crust beneath the
fracture zone is 1 to 2 km thinner. They also found a thick
section of mid- to lower crust with P wave velocities of 6.6
to 6 km/sec, similar to that of normal oceanic crust. The
results of Sinton and Hussong [1983] also suggest that
slower mantle underlies the region east of the spreading
ridge relative to that in the west (Vp = 7.5 vs. 8.0 km/sec).

Mariana Trough crust thickens north of 21°N. Gravity
data were interpreted by Ishihara and Yamazaki [1991] to
indicate that the crust thickens from 6 to 9 km near 21°20′N
(Region III, Figure 14A&C) to about 15 km near 23°30′ to
24°N (Region I, Figure 14A&C). This is also the part of the
Mariana Trough where the extension axis shoals from about
3.5 km depth to about 2.0 km depth. Recovery of mantle
peridotite from deep graben near 20°N [Stern et al., 1996]
shows that the crust is thin at least this far north, and the fact
that the extension axis shoals north from this point also sug-
gest crustal thickening to the north.

7.2. The Forearc

The IBM forearc is about 200 km wide and differs from
many other forearcs by not having an accretionary prism.
This is because IBM is isolated from continent-derived sed-
iments. In addition, because the supply of sediments to the
IBM forearc is limited to pelagic ‘rain’ and volcanioclastics
shed from the volcanic arc, the infrastructure of especially
the outer forearc is not deeply buried. The relatively naked
IBM forearc provides unique opportunities to sample the
rocks that formed when subduction began, to track the evo-
lution of Subduction Factory products, and to examine flui-
ds squeezed and sweatied out of the downgoing slab.

There are important differences along the IBM forearc
that reflect its evolution and relative tectonic stability. The
treecold subdivision proposed for the IBM arc system in
Section 2 provides a useful subdivision for the forearc
region as well. The Izu section has no well-developed
frontal arc ridge comparable to those of the Bonin and
Mariana segments (Figure 4). The long stability of the Izu forearc is demonstrated by several well-developed submarine canyons up to 150 km long across the forearc which began to form in early Miocene time [Klaus and Taylor, 1991]. The few conical features near the trench that are likely to be serpentine mud volcanoes are covered with pelagic sediments and seem to be inactive, for example Torishima seamount drilled during ODP Leg 125. The Bonin forearc is characterized by a well-developed forearc basin (Bonin Trough), which formed as a result of Oligocene rifting [Taylor, 1992]. The forearc basin becomes progressively more filled or poorly developed away from the Bonin segment, and the free-air gravity expression of the Bonin Trough becomes muted [Honzza and Tamaki, 1985]. The Bonin Ridge is capped by the Bonin or Ogasawara islands and is associated with one of the highest free-air gravity anomalies on Earth (up to 360 mGal) [Honzza and Tamaki, 1985].

Dredging of the IBM inner trench wall has recovered mostly igneous rocks, including peridotites, boninites, and arc tholeiites [Bloomer, 1983; Bloomer and Hawkins, 1987; Ishii, 1985; Tararin et al., 1987]. Similar sequences of boninite and arc tholeiite were penetrated during DSDP and ODP drilling [Hickey and Frey, 1982; Pearce et al., 1992]. These rocks are interpreted as forming during the initial stages in the development of the IBM subduction zone during Eocene time [Stern and Bloomer, 1992]. There is also evidence that pre-Eocene rocks make up a small portion of the forearc basement, including Pacific MORB crust [Debari et al., 1999] and accreted Cretaceous seamounts and pelagic sediments [Bloomer and Hawkins, 1983; Johnson et al., 1991].

The frontal arc islands of the southern Marianas (Guam, Saipan, etc.) and the Bonin Islands (Chichijima, Hahajima, etc.) provide an opportunity to study forearc evolution in detail. These islands show the same sort of tholeiitic/boninitic igneous basement as that found in the submerged forearc [Hickey-Fargas and Reagan, 1987; Reagan and Meijer, 1984; Taylor et al., 1994; Umino, 1985], although the island sequences also have abundant low-K rhyodacites [Meijer, 1983; Taylor et al., 1994]. The northern Bonin Islands are dominated by boninite series volcanics whereas the southern Bonin Islands consist of tholeiite and calc-alkaline lavas [Taylor et al., 1994], demonstrating an intermingling of magma types similar to that observed downhole in DSDP Site 458. The Eocene volcanic sequences in the Bonin Islands are overlain by shallow water limestones of Oligocene-Early Miocene age [Taylor et al., 1994]. Mariana frontal arc islands have a more complete record of the interplay between seafloor and tectonics in a well-developed sequence of reefal limestones of Oligocene to Holocene age [Cloud et al., 1956; Tracey et al., 1964]. The Balanos volcanic member of mid-Miocene age (13.5 Ma) on Guam [Meijer et al., 1983] is part of a thicker sequence of volcanic and sedimentary rocks known as the Umatac Formation. This is the on-land equivalent of the thick Miocene ash blanket drilled at DSDP Site 60 and corresponds to the mid-Miocene magmatic maximum identified by Lee et al. [1995].

The Mariana forearc is tectonically unstable, reflecting the combined effects of stretching parallel to it due to being 'bowed-out' by back-arc extension and because of oblique convergence (Figure 6; [McCaffrey, 1996; Stern and Smoot, 1998]). A detailed survey of the inner forearc near 22°N [Wessel et al., 1994] confirmed that the northern Mariana forearc is dominated by sinistral shear [McCaffrey, 1996]. This tectonic instability is an important reason why the Mariana forearc has no identifiable submarine canyons and is also the main reason why fluids and serpentinitized mantle
rise to the surface at several places here. Because an important motivation for selecting IBM as a MARGINS focus area was that this is the only place known where we can sample fluids released at shallow depth from a subduction zone, we concentrate in the following discussion on the Mariana forearc (Figure 15).

![Figure 15. The IBM forearc, between 13° and 25°N, shown in gray. Generalized structural features and location of serpentinite mud volcanoes are taken from Stern and Smoot [1998]. Dashed line marks the boundary between rough and smooth terrains of Stern and Smoot [1998], or between Eastern and Western Structural Provinces of Mrozowski and Hayes [1980]. Arrows radiating out from the back-arc basin extension axis show how differential extension causes decreasing radius of curvature of the arc, leading to stretching of the forearc along strike. Location of DSDP sites 60, 458, 459, 460, 461, and 1200 are shown. ODP sites 778-781 are centered on Chamorro Seamount. Names of serpentinite mud volcanoes, after Frayer et al. [1999] from south to north: South Chamorro, SC; North Chamorro, NC; Blue Moon, BM; Peacock, Pe; Celestial, C; Turquoise, T; Big Blue, BB; Pacman, Pm; Conical, Co.](image)

Mariana forearc seafloor is relatively smooth in its western 2/3 and rugged seafloor in its eastern 1/3. The inner, smooth forearc slopes gently eastward and lies mostly 3 to 4 km below sealevel, reflecting deposition of distal volcaniclastic turbidites, ash, and pelagic sediments. In contrast, the outer, rugged forearc has a mountainous local relief of over 2 km. Rough and smooth forearc sectors correspond to the eastern and western structural provinces of Mrozowski and Hayes [1980]. The western structural province is typified by a thick sequence of well-stratified, relatively undeformed sediments above an eastward-shoaling basement reflector, comprising a forearc basin. This basin is over 3 km thick in the flexural moat cast of the active volcanic arc [Mrozowski and Hayes, 1980] and is filled with relatively undeformed sediments as old as latest Eocene or early Oligocene [Hussong and Uyeda, 1982]. A basaltic sill of Late Miocene or younger age was penetrated at ODP site 781A, near Conical Seamount (Figure 15,16) [Marlow et al., 1992], and forearc volcanic flows and intrusions likely comprise a minor part of the Mariana forearc basin sequence. Although the Mariana forearc basin is structurally much simpler than the rugged region to the east, it is cut by numerous high-angle normal faults that parallel the arc and trench, with surface offsets that range from 10 to 250 m. Intersection of acoustic basement with the seafloor defines the eastern limit of the forearc basin and the boundary between the western and eastern structural provinces.

The IBM forearc has been drilled during DSDP Legs 6 and 60 and ODP legs 125, 126, and 195 (Figure 15 & 16). DSDP Site 60 penetrated 350 m without reaching basement, with the interval from 50-350m consisting of Miocene ash [Party, 1971]. DSDP Leg 60 drilled four holes in the forearc. Site 458 penetrated almost 500m, with the upper half consisting pelagic sediments and ashes reaching back to the early Oligocene and the lower half consisting of pillowed tholeiites and boninites of probable Eocene age [Party, 1982a]. Site 459 penetrated almost 700m, with the upper 560 m consisting of pelagic sediments and ash beds as old as middle Eocene, underlain by pillowed tholeiites of middle Eocene and older age [Party, 1982b]. Site 460/460A penetrated about 100m of Pleistocene diatomaceous ooze, Oligo-Miocene conglomerates, and vitric muds of Eocene to Oligocene age. Site 461, near the trench axis, penetrated 21m of Quaternary conglomerate. ODP sites 779-781 were all drilled within 15 km of the summit of Conical Seamount (Figure 16). ODP site 1200 penetrated 200m into the South Chamorro mud volcano and installed a borehole geophysical observatory. In addition to these sites in the Mariana forearc, ODP sites 782-793 were drilled near 31-32°N in the northern IBM forearc.
The rugged, outer Mariana forearc contains several serpentinite mudvolcanoes, some of which are active (Figure 15). Conical Seamount is a good representative of these. This edifice is 10-15 km in diameter and 1500m tall (Figure 16). Young flows mantle its flanks and extend as far as 18 km from the summit area [Fryer et al., 1990a]. The youngest flows are light green, have contorted surfaces, and are not covered with pelagic sediments. They contain numerous cobbles and boulders, mostly of serpentinitized peridotites and dunites, with small amounts of metabasalt and metagabbro. Vent chimneys composed of carbonate (aragonite and calcite) and hydrated Mg-silicate are found near the summit region (Figure 16). The carbonate chimneys and concretions are unusual in being composed of aragonite well below the aragonite compensation depth in this region (~400m). Haggerty [1991] concluded that these carbonates were not precipitated in equilibrium with seawater; furthermore, isotopically light C indicates equilibrium with methane. Compared to ambient seawater, fluids emanating from vents in the summit area are slightly cool-
er (0.03°C) and have higher pH (9.3 vs. 7.7) and alkalinity (5.5 vs. 2.4 meq/L). The vent waters are enriched in methane (1000 vs. 2.1 nM), silica (0.75 vs. 0.12 mM), and H₂S (2.1 mM vs. none detected) [Fryer et al., 1990a]. A biogenic origin for the methane enrichments was discounted by Fryer et al. [1990a] because of the lack of a sedimentary substrate where bacteria could thrive, but the possible role of a deep biosphere was not considered at that time.

ODP Leg 125 drilled four holes in and around Conical Seamount (Figure 16). Sites on Conical Seamount recovered cores of unconsolidated serpentinite mud matrix containing aragonite needles and blocks of mafic and ultramafic lithologies [Fryer, 1992]. Pore waters from Site 780 (summit of Conical Seamount) are some of the most unusual ever sampled in oceanic sediments, containing less than half of the chloride and bromide concentrations of seawater, pH up to 12.6, and contain methane up to 37mmol/kg along with ethane and propane [Mottl, 1992]. Relative to seawater, these fluids are enriched in alkalinity (x26), sulfate (x1.7), K (x1.5), Rb (x5.6) and B (x10) and are depleted in Li, Mg, Ca, and Sr. Although low in Na, these pore waters have Na/Cl ratios about twice that in seawater. Sr isotopic compositions of pore waters are significantly less radiogenic than seawater and become less radiogenic down core [Haggerty and Chaudhuri, 1992]. Some aspects of the fluids can be explained as a result of interaction with peridotite. However, the decrease in chlorinity of the pore fluid at Site 780D is greater than observed in pore fluids from any other convergent margin. Mottl [1992] concluded that the fluids at Conical Seamount originated from the downgoing slab, 30 km beneath the seafloor, and agreed with Sakai et al. [1990] that this water was also responsible for serpentinizing the overlying mantle wedge.

Ultramafic blocks encountered in the serpentinite mud are largely serpentinitized but often preserve original igneous minerals such that their original nature can be inferred. Refractory peridotites dominate (mostly harzburgite, minor dunite) [Ishii et al., 1992]. Orthopyroxene and olivine have Mg# ~ 92. Spinels in the harzburgite are generally more Cr-rich than those found in MORB-type abyssal peridotites [Dick and Bullen, 1984], indicating that these are residues left after extensive melting. These peridotites are similar to those recovered from the Mariana inner trench wall. Parkinson and Pearce [1998] interprets the trace element signature of Conical Seamount harzburgites as residual MORB mantle (15-20% fractional melting) subsequently modified by interaction with boninitic melt. Intriguingly, recent Os isotopic data give a mixture of modern and ~1 Ga model ages for both Conical and Torishima seamount harzburgites [Parkinson et al., 1998].
Mafic crustal blocks are about 10% as common as peridotite blocks in ODP cores drilled at Conical Seamount [Johnson, 1992]. Basalt compositions have both arc- and MORB-like affinities. Metamorphism in most samples ranges from low-T zeolite to lower greenschist facies. At site 778A, Maekawa et al. [1993] documented clasts containing blueschist-facies mineralogy (lawsonite, aragonite, sodic pyroxene, and blue amphibole) and used these to estimate metamorphic conditions of 150-250°C and 5-6 kbar. This is the first direct link documented between an active subduction zone and blueschist-facies metamorphism.

It is not clear what routes solids and fluids follow upward to feed the mud volcanoes. Some authors infer diapirc upwelling [Phipps and Balloti, 1990], whereas others infer that ascent is localized along fault intersections [Fryer, 1996a]. Regardless, the serpentine muds are weak plastic materials with low density and strengths and are easily mobilized [Phipps and Balloti, 1990]. These authors also noted that, although these muds can transport blocks of serpentinitized peridotite as large as 20m upward, such blocks would sink unless the mud continues to upwell. Fluids appear to be upwelling faster than a few mm/yr [Mottl, 1992]. The identification of slab-derived fluids and solids requires that ascent paths must reach down to the slab itself.

Recent attention has been focused on South Chamorro seamount, the southernmost of IBM serpentinite mud volcanoes (Figure 15). This is the site of active venting, which supports a vigorous biological community of mussels, snails, tube worms, and crabs, that is far richer than the Conical Seamount community [Fryer and Mottl, 1997]. The muds are predominantly serpentinite but also contain blue, sodic amphiboles (crossite), jadeite, and hydrated garnet. South Chamorro is also the ‘southem forearc seamount’ where Haggerty [1991] reported very light C from chimney materials and interpreted this to indicate equilibrium with organic methane. South Chamorro seamount was drilled during ODP Leg 195 in March, 2001 (http://www.odp.tamu.edu/80/publications/prelim/195_prel/195toc.html).

Recent samplings of fluids from serpentinite mud volcanoes built at different heights above the subduction zone suggest that systematic variations in fluid chemistry can be identified. These are interpreted to manifest progressive decarbonation reactions in the downgoing slab [Fryer et al., 1999]. Pacman Seamount, situated ~15km above the subduction interface, vents fluids with low alkalinity and is associated with brucite chimneys, whereas vent fields on S. Chamorro (~20km above the subduction interface) and Conical seamounts (~25 km above the subduction interface) issue fluids with much higher alkalinity and have chimneys of carbonate and silicates. Fryer et al. [1999] infer from this relationship that important decarbonation reactions happen in the slab when the subduction interface above it lies at 15-20 km depth.

The IBM forearc may host an ultra-deep biosphere. If the ultimate limit on life is high temperature, then life may exist to greater depth in cold subduction zone environments than anywhere else in the planet. Intense fluid mediation of the relatively cool forearc may support the deepest biosphere in the planet. No data exists to support this speculation.

7.3. The Magmatic Front

The magmatic front lies at a height of about 150 km above the Wadati-Benioff zone, with no systematic differences along the IBM arc system. Estimates of magmatic production rates vary widely, largely because these are based on different models. Looking just at volcanics, Sample and Karig [1982] estimated a production rate of 12.4 km³/Ma/km for the Mariana segment. Plutonic equivalents and cumulates need to be included to obtain a magmatic production rate, but the ratio of intrusive to extrusive igneous products is poorly constrained. This uncertainty is shown by differing estimates of crustal growth rates of 70-80 km³/Ma per km of arc estimated for the northern IBM arc [Taira et al., 1998] and 30 km³/Ma per km of arc estimated for Phanerozoic arcs [Reymer and Schubert, 1984]. Resolving the magmatic addition rate to the IBM arc is a critical constraint needed to understand IBM Subduction Factory processes.

Both submarine and subaerial volcanoes define the IBM magmatic front (Figure 2). On this basis, the Mariana segment has been subdivided into Northern Seamount Province, Central Island Province, and Southern Seamount Province [Bloomer et al., 1989b]. It is still not clear where the southern IBM magmatic arc ends [Martinez et al., 2000]. Photographs of individual subaerial volcanoes of the IBM arc can be seen on-line at Volcano World (http://volcano.und.nodak.edu/vwdocs/volc_images/north_asia/Izu-Volcanic-Islands/Izu1.html; Iwo Jima: http://volcano.und.nodak.edu/vwdocs/volc_images/north_asia/iwo-jima.html; Mariana islands: http://volcano.und.nodak.edu/vwdocs/volc_images/southeast_asia/mariana/basic_geology.html).
phenocrysts are tholeiites [Jackson, 1993; Lee and Stern, 1998]. Primitive compositions (Mg#>65) are uncommon among IBM arc lavas, so fractionation conditions and history need to be resolved.

A related issue that awaits resolution is the abundance of felsic material in the IBM arc. Like all IOCM, IBM is commonly thought to have a basaltic bulk composition. Recent evidence from geophysics [Suyehiro et al., 1996], exposures in the IBM collision zone [Kawate and Arima, 1998], glass inclusions in phenocrysts [Lee and Stern, 1998], the abundance of felsic tephra in DSIP cores [Lee et al., 1995], and the presence of submarine silicic calderas in the Izu segment [Iizasa et al., 1999] indicates that felsic rocks are a more important part of the IBM arc system than previously thought.

7.3.1. Elemental abundances. A key element for understanding operation of the IBM Subduction Factory is knowing the typical compositions and regional variability in magma compositions along the magmatic front of the IBM arc. An EXCEL spreadsheet, available upon request to the first author, was constructed for 62 volcanoes from along the magmatic front of the IBM arc system, from Oshima (34.73°N) to an unnamed seamount west of Rota (14.33°N). This compilation is not exhaustive; instead data were entered for samples which contained information considered to be especially important, such as high-quality data for REE, HFSE abundances (Y, Zr, Nb, Ta), or isotope data (B, Li, Be, O, Sr, Nd, Pb, Hf). Data were assembled from the literature [Bloomer et al., 1989a; Dixon and Stern, 1983; Eiler et al., 2000; Elliott et al., 1997; Hamuro et al., 1983; Hochstaedter et al., 2001; Ishikawa and Nakamura, 1994; Ishikawa and Tera, 1999; Lin et al., 1989; Lin et al., 1990; Morimoto and Ossaka, 1970; Notsu et al., 1983; Pearce et al., 1999; Stern and Bibe, 1984; Stern et al., 1989; Stern et al., 1993; Stern et al., 1984; Sun and Stern, 2001; Sun et al., 1998a; Sun et al., 1998b; Taylor and Nesbitt, 1998; White and Patchett, 1984; Woodhead, 1989; Yuasa and Nohara, 1992; Yuasa and Tamaki, 1982]. Means were calculated for each of these volcanoes (volcano means) despite big differences in the number of samples from which means are calculated, from a minimum of 1 to a maximum of 20. Means for the entire IBM system assume equal weighting for each volcano mean. These means are the basis for the following overview.

IBM lavas from along the magmatic front of the arc show a wide range of compositions. For example, volcano means plot in the low-K, medium-K, high-K, and shoshonitic fields on potassium-silica diagrams (Figure 17). Low-K suites characterize the Izu and most of the Bonin segment (as far south as 25°N), a medium-K suite typifies most of the Mariana segment (as far north as 23°N), and a largely shoshonitic province is found between the Bonin and Mariana segments. This subdivision will be used in subsequent discussions of along-arc compositional variations, and symbols on figures correspond to this first order variation. Volcano means scatter unsystematically around a mean for the volcanic front of 55% SiO2 (Figure 18B), indicating that these lavas are generally quite fractionated. Although the major element variations along the arc are systematic, the significant variations in composition do not correspond exactly to the along-arc subdivisions shown on Figures 1 and 2. One variation that does seem consistent with this segmentation is the abundance of large submarine silicic calderas in the Izu segment; where nine are found [Iizasa et al., 1999], in contrast to the absence of this volcanic style in the rest of the IBM arc. Along-arc variations in potash concentrations (Figure 18C) show that this variation is not related to fractionation, with high K lavas in a different place than the high SiO2 lavas. The low potassium contents of Izu segment lavas is reflected in the fact that some of the felsic volcanoes have mean potash contents below the IBM arc mean of 0.98% K2O.

Determining water and CO2 contents of arc lavas has proved challenging because arc lavas are extensively degassed. Water contents determined for ten glass inclusions in phenocrysts from three volcanoes average 2.2% H2O accompanied by no detectable CO2 (except for 400-600 ppm in one shoshonite). Water contents in glass inclusions in a gabbroic xenolith from Agriag gives a mean of 5.1% H2O and negligible CO2 [Newman et al., 2000]. It is not clear whether the much higher value for the xenolith better reflects magmatic water contents or post-entrapment crystallization, but an estimate of 3% H2O in IBM magmas.

Figure 17. Potassium-silica diagram for the mean composition of 62 volcanoes along the magmatic front of the IBM arc system. Data sources discussed in text. Names for rocks indicated for calc-alkaline and tholeiitic series below the double arrows, above the double arrows for the shoshonitic series.
prior to degassing seems conservative at this time. Water contents of northern IBM arc magmas are unknown.

There are important differences in source depletion observed along the arc. Because Zr behaves more incompletely than Y for most mantle minerals, the ratio Zr/Y is relatively high in melts generated from undepleted mantle sources and decreases for melts from depleted sources. A similar relationship holds for Nd/Sm. The mean Zr/Y for the arc system is 3.3, slightly higher than the MORB mean of 2.9 [Hofmann, 1988]. Similarly, the Nd/Sm ratio monitors source depletion, with higher Nd/Sm indicating a less-depleted source. The mean Nd/Sm for the arc system of

Figure 18. Profiles of mean silica and potash contents and Zr/Y and Nd/Sm for volcanoes along the magmatic front of the IBM arc. Data sources as described in text, same symbols as in Figure 17. A) Variations in bathymetry along the same profile, similar to Figure 2. Along-strike variations in silica B) and potash C) are shown, using symbols as in Figure 17. Mean silica and potash contents are shown for the IBM magmatic front as a dashed line. Along-strike variations in Zr/Y D) and Nd/Sm E) are shown, using symbols as in Figure 17. Mean values for Zr/Y and Nd/Sm are shown for the IBM magmatic front as a dashed line labeled Mean and also for typical MORB [Hofmann, 1988].
3.77 is also slightly higher than that for N-MORB (3.0) [Hofmann, 1988]. Following this simple argument, Figures 18D and E show that Izu-Bonin arc melts are derived from the most depleted sources, that Mariana arc melts are generated from somewhat less-depleted sources, and that lavas of the Shoshonitic Province are generated from an enriched source.

Differences between typical mafic lavas of the three arc segments are shown another way in Figure 19, along with the field of subducted sediment generalized from Figure 8. The three arc patterns are broadly similar in being greatly enriched in LIL elements (Rb, Ba, K, Pb, and Sr) and significantly depleted in HFSE Nb and Ta relative to MORB.

The patterns for Izu and Mariana are very similar except that the Izu lavas are generally more depleted for elements to the left of (more incompatible than) Sm. The shoshonitic pattern is similar to the features shown by the Izu and Mariana patterns, albeit at generally elevated levels. All three patterns broadly parallel the field defined by subducted sediment except that the positive anomaly for Sr in the lavas is not seen for the sediments. Another important feature of the pattern shown in Figure 19 for IBM arc lavas is that heavy REE elements are generally less abundant than in MORB. This is interpreted to reflect higher degrees of melting for IBM arc melts relative to MORB; it is estimated that IBM arc melts represent 25-30% melting of mantle peridotite [Bloomer et al., 1989a; Peate and Pearce, 1998]. Alternatively, the source peridotite may have been melted previously, beneath the back-arc basin spreading axis and then been remelted beneath the arc [McCulloch and Gamble, 1991]. However, if this is the dominant mechanism to explain the depleted nature of arc melts, one would expect the Mariana arc—which is associated with an actively spreading back-arc basin—to erupt more depleted lavas than the Izu arc, which has not been associated with an actively spreading back-arc basin for 25 million years. This is not the case: Izu segment lavas are significantly more depleted than Mariana segment lavas.

7.3.2. Isotopic characteristics A wide range of isotopic tracers have been applied to the IBM arc system since the pioneering studies of Hart et al. [1972] and Meijer [1976]. Some isotopic systems allow subducted components to be unequivocally identified in the source region of IBM arc melts, while others do not allow such contributions to be identified. Uncertainties in our understanding of the nature of the mantle source as it existed before the subduction component was added looms over all interpretations of the isotopic datasets. Regardless of these issues, the isotopic database provides one of the most important constraints that we have for how the IBM Subduction Factory operates. Accordingly, the isotopic database is summarized below, in order of increasing atomic weight.

There has not been a lot of He isotopic work, principally because of the difficulty of finding samples that have not been extensively degassed, but work on olivine separates promises to overcome this problem because glass inclusions in these retain volatile elements. This also applies to the other rare gases (Ar, Ne, Xe). A small amount of He data is presented by Poreda and Craig [1989], who report $^{3}$He/$^{4}$He of 7.22-7.65 x atmospheric values for three Mariana volcanoes, very similar to values for MORB of 8±1 x atmospheric. It appears that He in the arc lavas is overwhelmingly derived from the mantle.

Li and B isotope data for convergent margin lavas are powerful ways to identify contributions from altered oceanic crust. The first Li isotope data for the IBM arc system were reported by Morisugi and Nakamura [1998]. They noted that lavas from Oshima in the northernmost IBM arc have significantly heavier Li than do lavas generated by unmodified mantle, indicating significant participation of altered oceanic crust in the source region of melts beneath the magmatic front. They also noted that Li isotopic compositions decrease away from the trench, indicating decreasing involvement of altered oceanic crust. There is a larger database for B isotopic compositions of lavas from along the IBM arc magmatic front, which is significantly heavier (mean $\delta^{11}$B = +4.8%) than expected for unmodified mantle (Δ$^{11}$B<1‰; Figure 20A). This isotopic system is especially powerful because compositions expected for sediments, altered oceanic crust, and unmodified mantle are

![Figure 19. Incompatibility plot for lavas from along the front of the IBM arc. Typical compositions for the Mariana arc (GUG-9 of Elliott et al. [1997]; 51% SiO$_2$) and Shoshonitic province (54H of Peate and Pearce [1998]; 47.8% SiO$_2$) are plotted, along with a mean calculated for Izu arc mafic lavas (51.6% SiO$_2$ [Taylor and Nesbitt, 1998]). Symbols are the same as in Figure 17 (filled circles: Izu-Bonin; diamonds: Shoshonitic Province; open squares: Mariana). Composition of MORB and element order is after N-MORB of Hofmann [1988]. Grey field outlines the composition of IBM subducted sediment, from Figure 8.](image-url)
Figure 20. Isotopic variations along the IBM arc. Symbols are the same as in Figure 17 (filled circles: Izu-Bonin; diamonds: Shoshonitic Province; open squares: Mariana). (A) B isotopic variations; data for IBM arc after Ishikawa and Nakamura [1994] and Ishikawa and Tera [1999]; data for Mariana Trough basalts after Chaussidon and Jambon [1994]. Isotopic composition of altered oceanic crust, sediment, and mantle are from Ishikawa and Tera [1999]. (B) S isotopic composition of IBM arc lavas, Mariana Trough, and Sumisu rift lavas. Data for IBM arc lavas from Alt et al. [1993], Ueda and Sakai [1984], and Woodhead et al. [1987]; Data for ten Mariana Trough basalts are from Alt et al. [1993]; for 7 Sumisu Rift lavas from Hochstaedter et al. [1990a]. Fields for sediments, altered oceanic crust, and mantle are from Alt et al. [1993]. (C) Sr isotopic data for IBM arc lavas, normalized to E&A SrCO3; data sources described in text. (D) Nd isotopic data for IBM arc lavas, adjusted to a common value for the La Jolla Nd standard; data sources described in text.
distinct. The heavy B isotopic composition of IBM arc lavas indicates that most B is derived from altered oceanic crust, although progressive metamorphism of subducted components will leave progressively heavier B and other light elements in the slab as distillation proceeds. In contrast, two samples from the Mariana Trough plot in the field expected for mantle-derived rocks or sediments. Considered together, Ll and B isotopic data available for the IBM arc indicate that subducted altered oceanic crust makes important contributions to the source of melts generated along the magmatic front.

$^{10}$Be is another important isotopic tracer. Because it is cosmogenic, with a 1.5 million year half-life, it is only found in very young sediments. Because subduction to depths of $\sim 130$ km is a few to several million years, significant amounts of $^{10}$Be in fresh arc lavas demonstrates that recycling of sediments takes place. Studies to date of IBM arc lavas indicate very low abundances of $^{10}$Be compared to other arcs [Woodhead and Fraser, 1985], due in part to low sedimentation rates outboard of the IBM trench.

Oxygen isotopic data for the IBM arc system has resulted in some controversy. This is an important tracer because O is the most common element in igneous rocks and because there are big differences in the isotopic composition of mantle ($\delta^{18}$O $\sim +5.7 \%$) and sediments ($\delta^{18}$O $\sim +20 \%$). The first study [Matsuhisa, 1979] concluded that fresh basalts from Oshima and Hachijo-jima had $\delta^{18}$O $= +5.3$ to $+6.1 \%$, indistinguishable from that of normal mantle. Matsuhisa [1979] observed a covariation of $\delta^{18}$O with SiO$_2$ that could be modeled by simple fractional crystallization. Similar observations were made in the southern IBM arc system by Ito and Stern [1986], who interpreted their data to limit the participation of sediments or sediment-derived fluids to $< 1\%$ of the oxygen budget. In contrast, Woodhead et al. [1987] concluded that Mariana arc lavas had distinctly lower $\delta^{18}$O than would be expected from melting of unmodified mantle, and that the participation of subducted sediment could be identified. One concern is that minor alteration of lavas can cause slight but significant shifts in oxygen isotopic composition, and some of the differences between the results of the different groups may have been due to this effect. The oxygen isotopic composition of IBM arc lavas has recently been re-examined by Eiler et al. [2000], who analyzed olivines and concluded that the oxygen isotopic composition of pristine Mariana arc lavas—including shoshonites—could not be distinguished from that of MORB or OIB melts. They concluded that no more than 1% or so of the oxygen in these rocks could be recycled from subducted sediments.

In contrast to the mantle-like oxygen in arc lavas, sulphur isotopic compositions are often elevated relative to mantle-derived rocks, particularly for the Mariana arc. Sparse data for Iwo Jima and Izu-Bonin segments are more mantle-like, or perhaps similar to altered oceanic crust (Figure 20b). Mariana arc samples approach the isotopic composition expected for sulphur in subducted sediments [Alt et al., 1993]. Fresh lavas from both the Mariana Trough and the Sumisu rift erupt lavas with mantle-like sulphur isotopic compositions [Alt et al., 1993; Hochstaelder et al., 1990a].

Sr comprises the most complete isotopic data set for the IBM arc (Figure 20C). $^{87}$Sr/$^{86}$Sr varies between 0.7030 and 0.7040, with a mean value of 0.70352. This is more radiogenic than the mean of 0.7028 found for MORB [Ito et al., 1987] or the mean of 0.70304 found for Mariana Trough back-arc basin basalts, but it is similar to the isotopic composition of OIB. Whether the more radiogenic composition of IBM arc lavas relative to MORB reflects the mixing of Sr from subducted materials into a depleted MORB-like mantle or manifests extraction of these melts from an unmodified OIB-like mantle remains controversial. Because of the completeness of the Sr-isotope dataset, long-wavelength variations can be identified. Most of the Mariana Arc and Izu-Bonin segments cluster around a mean of 0.7034 but volcanoes in the shoshonitic province along with the northernmost part of the Mariana arc cluster around 0.7038. Whether the elevated $^{87}$Sr/$^{86}$Sr of lavas from the shoshonitic province is due to the involvement of proportionately more or different subducted material or reflects mantle heterogeneities unrelated to subduction is unknown.

The database for Nd isotopic compositions of lavas from along the IBM arc is reasonably complete (Figure 20D). Isotopic data from the literature were adjusted to a common value of $^{143}$Nd/$^{144}$Nd for the La Jolla Nd standard, from which values of eNd were calculated. The mean for the arc system is +6.7, significantly lower than typical values for MORB of $\sim +10$. Variations along the arc mostly mirror variations seen for Sr isotopes, with the northernmost Mariana arc and shoshonitic province volcanoes having less radiogenic Nd (lower eNd) than the rest of the arc. This is consistent with a greater role for subducted sediments or derivation from enriched mantle, although Nd is generally thought not to be mobile in hydrous fluids like those sweat ed out of the subducting slab. Izu-Bonin arc lavas mostly have higher eNd than Mariana arc lavas. Compared to Mariana arc lavas, the higher eNd of Izu-Bonin lavas coupled with similar $^{87}$Sr/$^{86}$Sr results in the latter lavas lying significantly farther to the right than other IBM arc lavas, well to the right of where the mantle array would lie on Figure 21A if it were shown. This is strong evidence that subducted components (altered seafloor or sediments) help control the Sr systematics of the arc source region. For the most part, there is a clear break between the space occupied
Marinas and Shoshonitic Province. Pelagic sediments also lie above the NHRL on a plot of 208Pb/204Pb vs. 206Pb/204Pb plot (Figure 21C) and so have strongly positive D8/4. The complementary parameter D8/4 is not usually used to track sediment involvement, however, the IBM arc system shows systematic variations in D8/4 that differ in detail from those shown by D7/4 (Figure 22D). The arc system has a mean D8/4 ~14 and is even higher at the northern end of the Marianas and in the southern shoshonitic edifices. However, D8/4 drops precipitously for Iwo Jima and the southernmost Izu-Bonin segment before rising to a regional high over the northern Izu-Bonin segment. The strongly positive D8/4 over the northernmost IBM arc may be due to migration into the mantle beneath the northernmost IBM arc of Eurasian or Indian Ocean-type mantle that is distinguished by elevated D8/4 [Hickey-Vargas et al., 1995].

Uranium-thorium studies of IBM arc magmas provide important constraints on timescales and processes of fluid
fractionation, melt generation, and migration. These elements have similar distribution coefficients between mantle minerals and melt, but U is much more mobile than Th in oxidizing fluids. Such fluids can strip U preferentially from the subducted slab or the mantle and can correspondingly enrich the arc source region. Fractionation of U and Th is detectable in young lavas through the use of short-lived radiogenic daughter products. Striking confirmation that fluid-mediated fractionation has been important was demonstrated by the first U-Th disequilibrium study of IBM arc lavas [Newman et al., 1984]. Subsequent studies confirm that Mariana lavas generally contain large U-excesses [Elliott et al., 1997; Gill and Williams, 1990; McDermott and Hawkesworth, 1991]. These excesses vary systematically with composition. Lavas that have been interpreted to be derived from a depleted source to which a hydrous fluid was added (e.g., depleted arc tholeiites with high Ba/La) show large excesses in U, whereas shoshonites and lavas from relatively enriched sources show small to significant U-excesses (Figure 23B). Some samples show \((^{238}\text{U} / ^{230}\text{Th}) < 1\), which suggests small degrees of melting or long-term dynamic melting of sources with residual garnet or clinopyroxene [Turner et al., 2000]. Those samples showing strong fractionation of radionuclides lie near a 30 kyr isochron. This constrains the amount of time that has elapsed between fluid-mediated fractionation and eruption. Whether the timing of fluid mediated fractionation corresponds to dehydration of the slab, breakdown of amphiboles in the convecting mantle wedge, or some other event is not yet known.

Elliott et al. [1997] recently suggested that material was added from the subducted slab in two stages. Lavas with \((^{238}\text{U} / ^{230}\text{Th}) \sim 1\) have incompatible trace element abundances suggesting that their source has been metasomatized with a component from subducted sediments, possibly sediment melts. These workers also suggest that a late stage, water-rich component, with \((^{238}\text{U} / ^{230}\text{Th}) > 1\), was derived from altered crust and transferred to the mantle source region <30,000 years ago.

7.4. Cross-chains

Another perspective on IBM Subduction Factory outputs comes from considering chains of volcanoes that trend at high angles to the arc front, known as cross-chains. Because the Wadati-Benioff zone lies at different depths beneath cross-chain volcanoes while mantle and subducted material lie approximately on flowlines, the products of these volcanoes allow us to track output of the Subduction Factory across its breadth. Cross-chains are best developed in the Izu segment, where several extinct and one active cross chain are known. The Kan’ei, Manji, Empo, and Genroku cross-chains extend WSW between 30°30’ and 32°N (Figure 1) and give K-Ar ages between 3 and 12 Ma [Ishizuka et al., 1998]. Detailed geochemical and isotopic studies of these cross-chains are given by Hochstaedter et al. [2000; 2001], who concluded that magmas generated beneath the magmatic front had the strongest relative enrichments of fluid-mobile elements in spite of having the lowest concentrations of incompatible elements. Interestingly,
a similar study by [Tatsumi et al., 1992] concluded that Rb/Zr ratios increased away from the volcanic front, implying a greater role for slab-derived fluids in that direction.

Here we focus on the Zenisu and Kasuga cross-chains as active examples. The most impressive cross-chain in the IBM arc lies at its northern end, where five active or dormant subaerial volcanoes and submarine counterparts along the Zenisu Ridge extend about 300 km WSW from Oshima (Figure 24A). Volcanism along the Zenisu Ridge is dominated by rhyolitic eruptions. The islands of Kozushima and Nijima are dominated by medium-K rhyolitic rocks, with subordinate andesite and basalt [Aramaki and Itoh, 1993; Aramaki et al., 1993]. Mafic lavas dominate on Toshima [Taylor and Nesbitt, 1998]. Systematic variations in Li, B, Sr, and Pb isotopic compositions are consistent with decreasing participation of a slab-derived component away from the trench (Figure 24B-E; [Ishikawa and Nakamura, 1994; Moriguti and Nakamura, 1998; Notzu et al., 1983]). Moreover, the subducted component that dominates along the magmatic front can be identified on the basis of Li and B isotopes as subducted altered oceanic crust.

The Kasuga cross-chain, near 22°N, (Figure 1, 26B) is the best studied of any submarine arc volcano in the IBM arc system. It has been mapped with SeaMARC II imagery and sampled several times by dredging and 8 Alvin dives [Freyer et al., 1997]. The cross-chain consists of three volcanoes, Kasuga 1, 2, and 3, numbered with increasing distance from the magmatic front and increasing depth to the Wadati-Benioff zone. Kasuga 1 is extinct but Kasuga 2 and Kasuga 3 are active, with fresh lava exposures and hydrothermal activity at their summits. Kasuga 2 hydrothermal fluids are compositionally unique among submarine hydrothermal systems [McMurtry et al., 1993]. In contrast to lavas from the IBM magmatic front, Kasuga 2 and 3 lavas are often glassy and primitive; Mg# >65 is common. These lavas range from medium-K to shoshonitic suites and the basaltic range from nepheline-normative to hypersthene-normative [Stern et al., 1993]; this appears to be the only IBM cross-chain that has shoshonitic lavas. Much of the compositional range may be due to magma mixing [Meen et al., 1998]. Glassy margins of three Kasuga basalts contain 1.45-1.69% H2O [Newman et al., 2000]. Felsic volcanism is also important in the Kasuga cross-chain, although lavas with >66% SiO2 are not reported [Freyer et al., 1997]. U-Th disequilibrium studies show no U excess or even Th excess [Gill and Williams, 1990], indicating that fractionation of U-Th by hydrous fluids was not important. The range of δ18O for basaltic glasses (5.7 to 6.0‰) and clinopyroxene separates (5.23-5.57‰) indicates a mantle source, and the range for andesites and dacites (6.0-6.2‰; [Stern et al., 1993]) is consistent with their evolution by fractionation of basalt. These lavas do not show the elevated 87Sr/86Sr for a given εNd that is characteristic of lavas erupted along the magmatic front, and Pb isotopic variations and mantle-like Ce/Pb (10-23) limit the role of subducted sediment in modifying the mantle source region. Instead, the inverse variation of magma production rate and isotopic heterogeneity was interpreted by Stern et al. [1993] to indicate diminished melting with distance from the magmatic front due to diminished water supply from the subducted slab.

7.5. Magmatism Related to Extension

Extension-related igneous activity provides a third perspective on the high-temperature products of the IBM
Subduction Factory. This perspective is important not only because these volcanoes are located farther from the trench than the magmatic axis of the arc, but also because the melt generation process itself is different. Magma generation beneath the magmatic front is probably caused by fluid fluxing of downwelling mantle, whereas beneath back-arc basin spreading centers melting is probably caused by adiabatic decompression of upwelling mantle. Back-arc Basin melt generation is thus similar to that beneath mid-ocean ridges but aided by addition of water from the subduction zone (Figure 25). Evolution of an unfractured arc to one with a back-arc basin must thus be accompanied by reorganization of the underlying mantle flow, a problem that has not yet been explored. Also, mantle flow beneath an arc system associated with active back-arc basin spreading may carry mantle previously depleted by melting beneath the back-arc basin spreading center (1 in Figure 25B) to be remelted beneath cross-chains and the magmatic front (2,3 in Figure 25B) [McCulloch and Gamble, 1991].

Extension is manifested as inter-arc rift basins in the Izu segment [Klaus et al., 1992] and as an active back-arc basin (Mariana Trough) in the Mariana segment [Fryer, 1995]. Izu rifts may be earlier stages of tectonic evolution than that of a mature back-arc basin like the Mariana Trough. Here we briefly consider the magmatic products of the Sumisu Rift inter-arc basin and the Mariana Trough back-arc basin.

The Izu rift zone spans most of the Izu segment, from 33° to 27°30' N, just south of the Sofugan Tectonic Line, a distance of about 700 km. The rift zone parallels the arc magmatic front and lies just to the west of it, except near 29°N where magmatic arc and rift coincide (Figure 26A). Six basins have been named in the rift zone: Hachijo, Aogashima, Sumisu, Torishima, Sofugan, and Nishinoshima. The rift zone deepens southward, with flat, sediment covered basins lying at depths of a little deeper than 1 km in the north to little over 3 km in the south [Klaus et al., 1992; Taylor et al., 1991]. The Sumisu Rift is by far the best known of the Izu rifts and is representative. Studies of the Sumisu Rift include SeaMARC II and Seabeam swathmapping and Alvin diving [Taylor, 1992], multichannel seismic reflection profiling [Taylor et al., 1991] and ODP drilling (sites 790 and 791 in the basin, sites 788 and 789 on the flanking uplift to the east [Taylor, 1992]). This geophysical background provides a firm foundation for igneous rock geochemical studies [Fryer et al., 1990b; Hochstaedter et al., 1990a; Hochstaedter et al., 1990b; Ikeda and Yuasa, 1989; Gill et al., 1992]. Three oblique transfer zones divide the rift along strike into four segments with different fault trends and uplift/subsidence patterns. Differential strain is accommodated by interdigitating, rift-parallel faults and cross-rift volcanism, which is often concentrated at cross-rift transfer zones. The locus of maximum sediment thickness (>1 km) and basin subsidence occurs along an inner rift adjacent to the arc margin. Volcanism is also concentrated at highs between the basins, most of which mimic cross-chains extending W to SW from the major arc volcanoes, indicating the dominance of magmatic point sources. From estimates of extension (2-5 km), the age of the rift (~2 Ma), and accel-

![Figure 25](image_url). Conceptual models for evolution of the Subduction Factory from one lacking an actively spreading back-arc basin (A) to one associated with back-arc spreading (B). Note that magma generation and migration beneath the magmatic front occurs in a region of mantle downwelling, whereas that beneath the back-arc basin spreading axis occurs in a region of mantle upwelling. Note in (B) the multiple melting opportunities for mantle rising beneath the back-arc basin, with melt generation beneath the spreading axis (1), beneath cross-chains (2) and beneath the magmatic front (3). The IBM arc system presents all of these stages, with the Bonin segment now acting as an unfractured arc (A) whereas the Mariana segment is an outstanding example of an arc associated with back-arc spreading (B). The Izu segment represents an intermediate situation, where rifting is underway but has not proceeded to seafloor spreading. 
Figure 26. Actively extending systems of the IBM arc. A) Tectonic sketch map of Izu rifts, modified after Taylor [1992]; shaded where shallower than 3 km. Note this is rotated clockwise about 10° from true north. Calderas shown with open circles. Abbreviations for frontal arc volcanoes (from the north): Mt, Miyake Jima; Mk, Mikura Jima; HJ, Hachijo Jima; AS, Aogashima; MS, Myojin Sho; TS, Tori Shima; SF, Sofu Gan; NS, Nishino Shima. STL = Sofugan Tectonic Line. Abbreviations for rifts (from the north): HR, Hachijo Rift; AR, Aogashima Rift; SR, Sumisu Rift; TSR, Torishima Rift, SGR, Sofugan Rift; NSR, Nishinoshima Rift. B) Tectonic sketch map of the Mariana Arc and back-arc basin. Bathymetric contours are in km, region shallower than 3 km is shaded. CD = Challenger Deep, SSP = Southern Seamount Province, CIP = Central Island Province, NSP = Northern Seamount Province, K = location of Kasuga cross-chain, CG = Central Graben. Note that seafloor spreading characterizes the Mariana Trough south of 19°45′N and rifting is characteristic from this latitude north to Nikko, where the extension axis intersects the arc.

...continuing subsidence, Taylor et al. [1991] infer that the Sumisu rift is in the early stages of developing as a back-arc basin.

The Mariana Trough stretches 1300 km from north to south (Figure 26B), about the distance from Los Angeles to Portland, Tokyo to Seoul, or London to Rome, and has roughly the dimensions and areal extent of Japan or California. The Trough is crudely crescent-shaped, opening on the south; it is bounded to the east by the active Mariana arc, to the west by the remnant arc of the West Mariana Ridge [Karig, 1972], and to the south by the Challenger Deep part of the Mariana Trench. It narrows northward until the Mariana arc and West Mariana Ridge meet at about 24°N. It is widest in the middle, at 18°N, where it is about 240 km wide, and narrows to about half this at its southern, open end. Depths in the basin are distributed asymmetrically, being greater adjacent to the West Mariana Ridge than next to the active arc, due to a westward-thinning wedge of volcaniclastic sediments derived from the active arc, and also less thermal buoyancy of the mantle. Where not covered by sediments, the seafloor is deeper and bathymetry more rugged than normal. Zero-age seafloor of the Philippine Sea, including the Mariana Trough, lies at a mean depth of 3200 m compared to normal zero-age seafloor depths of 2500 m [Park et al., 1990].

The extension axis can be subdivided along strike into a southern two-thirds characterized by slow seafloor spreading and a northern third characterized by rifting (Figure 26B). From 19°45′N south to 13°10′N, the axis has the typical morphology of a slow-spreading ridge, with an axial graben that is sometimes occupied by a neovolcanic axial ridge [Hawkins et al., 1990; Martinez et al., 2000; Stüben et al., 1998]. South of this the ridge resembles a fast spreading ridge, probably because magma supply is enhanced by proximity to the arc [Martinez et al., 2000]. Spreading half-rates in the region between 16° and 18°N are estimated at 1.5 to 2.2 cm/year [Bibee et al., 1980; Hussong and Uyeda, 1982; Yamazaki and Stern, 1997]. The ridge becomes punctiform north of 18°30′, and true seafloor spreading does not occur north of 19°45′N (but see the different conclusion of Yamazaki et al. [1993]). Rifting forms a series of amagmatic deeps between 19°45′N and 21°10′N called the “Central Graben” by Martinez et al. [1995]. These basins have low heatflow, lack igneous activity, and contain the greatest depths in the Mariana Trough (>5400m). The deepest part of the Central Graben is also unique among active back-arc basins in exposing mantle peridotites along the extension axis [Stern et al., 1996]. Extension north of the Central Graben occurs by combined tectonic and magmatic processes that are distinct from seafloor spreading, in a region known as the Volcano-Tectonic Zone (VTZ) [Martinez et al., 1995]. The VTZ corresponds with a part of the Mariana Trough where the crust thickens from 6 to 15 km (Figure 14). The southern VTZ is dominated by fissure eruptions associated with a ridge-like feature, ~30 km long, which rises to less than 2800 m water depth and which is
similar to the inflated segment at the southern terminus of the spreading ridge. The northern VTZ is dominated by point-source volcanism, with edifices spaced 50-60 km apart alternating with rift basins. There is no volcanic activity along the adjacent arc segment and it appears that the extension axis has captured the arc magma supply between the Kasuga cross-chain at 22°N and Nikko near 23°N, where the extension axis intersects the arc. North of this point, incipient rifting is magmatically manifested by the shoshonitic lavas of the Hiyoshi complex, Fukutoku-oka-no-ba (or Sin Iwo Jima), and Iwo Jima (Figure 26B). Rifting and spreading propagate northward at a rate of 10 to 40 cm/year [Martinez et al., 1995; Stern et al., 1984], so the variations in tectonic and magmatic style seen along-strike north of 18°N reveal the sequence of events that occur as the back-arc basin rift evolves from upwelling through rifting to seafloor spreading.

The following geochemical discussion and data for associated figures is extracted from the following literature sources: [Hochstaedter et al., 1990a; Ikeda and Yuasa, 1989; Alt et al., 1993; Chaussidon and Jambon, 1994; Fryer et al., 1990b; Garcia et al., 1979; Gribble et al., 1996; Gribble et al., 1998; Hart et al., 1972; Hawkins et al., 1990; Hawkins and Melchior, 1985; Ikeda et al., 1998; Ito and Stern, 1986; Jackson, 1989; Poreda, 1985; Sano et al., 1998; Sinton and Fryer, 1987; Stern et al., 1990; Volpe et al., 1987; Eiler et al., 2000; Hochstaedter et al., 1990b; Macpherson et al., 2000; Newman et al., 2000]. Data for the Mariana Trough samples are entered in an annotated EXCEL database that is available from the first author upon request. Before summarizing the geochemical and isotopic signatures of extension-related IBM lavas, three points need to be emphasized. First, even though the Sumisu Rift is in the early stages of extension and seafloor spreading is not occurring, these basalts have geochemical and isotopic affinities with back-arc basin basalts such as erupt from spreading segments of the Mariana Trough [Hochstaedter et al., 1990b]. Second, and in contrast to the absence of felsic volcanism in the Mariana Trough spreading ridge, volcanism in the Sumisu Rift is compositionally bimodal, with abundant felsic (>70% SiO₂) material as well as basalt. The bimodal nature of Sumisu Rift igneous activity makes it more similar to the northern VTZ than to the spreading portion of the Mariana Trough (Figure 27A). Extension-related igneous activity in many tectonic environments is compositionally bimodal during rifting and becomes entirely mafic when seafloor spreading begins. Finally, extension-related lavas are wet, generally containing much more water than found in MORB or OIB. Glassy Mariana Trough basalts contain 0.2-2.78% H₂O, with a mean of 1.59%. This range does not seem to due to degassing, because glass inclusions

contain similar water abundances as found in glassy lava rims.

Extension-related basalts generally show chemical signatures of a 'subduction component' that is dominantly carried by a hydrous fluid. Trace element abundances vary strongly with how wet the melt was. Figure 27B presents trace element abundances for the two rifting segments, Mariana Trough VTZ and Sumisu Rift, along with end-member examples of basalts erupted along the Mariana Trough spreading ridge. As can be seen from this figure, some basalts in the Mariana Trough spreading segment

Figure 27. Chemical features of IBM rift-related lavas. A) Potash-silica diagram for IBM rift-related igneous rocks. Fields are shown for Sumisu and Myojinsho rifts (66 samples), Mariana Trough VTZ (41 samples), and Mariana Trough spreading segment (labeled MTB, 167 samples). Note the bimodal nature of lavas erupted in rifts and strictly mafic nature of lavas erupted in the region undergoing spreading. B) Incompatibility plot for extension-related IBM lavas. Sumisu rift data is mean from data set of Hochstaedter et al., 1990b; note that this pattern is incomplete. Mariana Trough data are for glasses analyzed by Pearce (unpublished ICP-MS data). VTZ sample is T7-54-1-1 (1.68% H₂O). Two representative samples are given for the Mariana Trough spreading segment: 'arc-like' sample GTVA75-1-1 (2.21% H₂O) and 'MORB-like' sample DS84-2-1 (0.21% H₂O) [Gribble et al., 1996]. Composition of N-MORB and element order is after Hofmann [1988]. Grey field outlines the composition of Mariana and Izu segment lavas, from Figure 19.
have trace element patterns—and concentrations of water—which are indistinguishable from MORB (labeled ‘MORB-like’ on Figure 27B). More commonly, Mariana Trough basalts from the spreading segment have an identifiable arc signature, especially enrichments in fluid-mobile elements Rb, Ba, K, Pb, and Sr, and elevated concentrations of water. This is particularly perplexing because the Mariana Wadati-Benioff zone dives nearly vertically and does not lie beneath most of the Mariana Trough, so how slab-derived fluids are transported to the melt generation zone is unclear. Arc-like geochemical features are ubiquitous in portions of the IBM arc system undergoing rifting. Melting models indicate that the degree of melting in spreading segment basalts (‘spread’ basalts) can be directly linked to the abundance of water in the mantle source [Gribble et al., 1998; Stolper and Newman, 1994].

In spite of the geochemical indications for a subduction component, isotopic data for Mariana Trough spread basalts mostly indicate a mantle source. Helium isotopes data indicate a mean R/R_A = 7.87±1.34 (1 std. dev.), indistinguishable from the value for MORB of 8±1. Two analyses of boron isotopes fall in the fields for the mantle (Figure 20A). Mean δ13C of -4.15±1.34‰ is close to mantle values as well. Oxygen isotopic data mostly on glasses gives a mean δ18O of +5.85±0.15‰, overlapping the range of 5.35-6.05‰ for MORB glasses [Ito et al., 1987], although glasses with strong arc-like signatures sometimes have δ18O of 6.0-6.1‰. Indications that Mariana Trough spread basalts have oxygen isotopic compositions that are indistinguishable from MORB is confirmed by analysis of olivines [Eiler et al., 2000]. Sulphur isotopic data for samples from both the spreading and VTZ segments of the Mariana Trough spread and the Sumisu Rift fall in the field for mantle-derived basalts (Figure 20B).

Isotopic data for Sr, Nd, and Pb indicate that the mantle source of rift volcanism is very similar to that of associated arc segments whereas spreading segments have distinct mantle sources. Figure 21A shows that the εNd of Sumisu Rift lavas is similar to Izu-Bonin arc lavas but that they have lower 87Sr/86Sr. Mariana Trough VTZ and spread basalts are not distinguished in Figure 21, but spread basalts have significantly lower 87Sr/86Sr (mean = 0.70291±0.00015) and higher εNd (8.9±1.1) than lavas erupted along the associated magmatic front (see Figure 20C,D: 0.70352, +6.7). Lavas erupted from the Mariana Trough VTZ have Sr- and Nd-isotopic compositions that overlap those of the magmatic front (0.70343±0.00032; +6.8±1.0). Pb isotopic compositions tell a similar story. On Pb isotopic diagrams, Sumisu Rift and Izu-Bonin arc lavas plot in restricted areas that overlap, and both show elevated 208Pb/204Pb relative to the NHRL. Mariana Trough VTZ lavas have mean 206Pb/204Pb (18.76±0.13) that is indistinguishable from the mean for the IBM arc of 18.85. In contrast, Mariana Trough spread basalts have less radiogenic and more variable 206Pb/204Pb (18.24±0.27) and show elevated 208Pb/204Pb relative to the NHRL. The radiogenic isotope data strongly indicate that IBM rift basalts are produced by parts and processes of the Subduction Factory that generally produce basalts along the magmatic front, but that spreading basalts are produced differently.

In summary, although arc lavas have affinities with continental crust and back-arc basin lavas are in most ways indistinguishable from MORB and oceanic crust, the source regions of these two magma stems are similar in many respects. In particular, both mantle source regions are strongly affected by a ‘subduction component’ that travels with water extracted from the subducted slab or sediments. Although arc and back-arc basin melts have very different modes of formation and tectonic environments of eruption, arc and back-arc basin lavas show similar enrichments in LIL elements, depletions of HFSE, and water contents. In spite of these affinities, significantly different isotopic compositions indicate that back-arc basin melts have less of an identifiable component from subducted materials than do arc lavas. Fluids from the slab that interact with the back-arc basin source are more equilibrated with asthenospheric mantle than those delivered to the arc source. There is a great need for quantitative chemical modeling in tandem with development of realistic models for mantle, fluid, and melt flow to explain these similarities and differences.

7.6. IBM Collision Zone

The IBM arc system in the north terminates against Honshu in the Izu Collision Zone (ICZ; Figure 28). This is one of the few examples on Earth of active collision and terrane accretion, and it provides outstanding opportunities to study strain partitioning during terrane accretion and the nature of middle and deep crust of an IOCM. The ongoing collision also presents a first-order geohazard; the Great Kanto Earthquake of 1923 had an estimated surface wave magnitude of 8.2. This earthquake had an epicenter SW of Tokyo and it devastated southeastern Japan, including the cities of Tokyo and Yokohama. The earthquake killed about 140,000 people and was probably caused by the collision. Uplift associated with the collision zone has resulted in the highest topographic relief in Japan; if submarine relief is considered, the total relief in the region is greater than that of the Himalayas [Niitsuma, 1989]. Collision-related uplift
Figure 21. Isotopic composition of Sr, Nd, and Pb for IBM arc lavas, including Sumisu Rift and Mariana Trough basalts. Data for IBM arc are averages for individual volcanoes, data for Sumisu Rift and Mariana Trough are individual analyses. Fields for sediments (shaded) and W. Pacific off-ridge volcanics (dashed), taken from Figure 9, are shown in B and C. Location of these diagrams is shown with dashed boxes on Figure 9. The Northern Hemisphere Reference Line (NHRL [Hart, 1984]) is shown for comparison.

by back-arc basin (Mariana Trough) and interarc basin (Sumisu Rift) lavas and those of the arc (Mariana arc, Shoshonitic province, Izu-Bonin arc). Most of the former have $^{87}\text{Sr} \div ^{90}\text{Sr} < 0.7032$ and most of the latter have $^{87}\text{Sr} \div ^{90}\text{Sr} > 0.7032$. A few back-arc basin (BAB) samples are more radiogenic and are isotopically indistinguishable from arc samples. These BAB samples are invariably from the northern rifted part of the Mariana Trough where the BAB extension axis is rifting, not spreading, and has captured the arc magmatic supply [Gribble et al., 1998].

A growing body of Hf isotopic data has been reported for the IBM arc system. The arc system has a mean eHf of 14 (Figure 22A). Variations in Hf isotopic composition along the arc are similar to those seen for Nd, with eHf decreasing markedly in the Shoshonitic Province. The data from the entire arc fall in the Nd-Hf mantle array of Vervoort and coworkers (Figure 23A). Pearce et al. [1999] used coupled Hf-Nd isotopic data to infer that the mantle source for IBM arc melts has always been of Indian Ocean provenance and that Pacific volcanogenic sediments make the most important contribution to the subduction component.

There are also considerable variations in Pb isotopic composition within the arc, most of which varies systematically along strike of the arc. Mariana arc lavas cluster around the mean $^{206}\text{Pb} / ^{204}\text{Pb}$ for the IBM arc of 18.85 (Figure 22B). Most of the shoshonitic edifices also cluster around this mean, with the exception of very radiogenic Iwo Jima data. This volcano defines a trend toward ‘HIMU’, possibly due to the participation of subducted HIMU off-ridge volcanoes (Figure 22C). Pb isotopic variations in the southern Izu-Bonin segment are radiogenic in the south but fall off rapidly to non-radiogenic values ($^{206}\text{Pb} / ^{204}\text{Pb} \sim 18.4$) at the north end of the IBM arc. Figure 21B and C shows the Pb isotopic data on a conventional Pb isotope diagram. The field of Western Pacific sediments (from Figure 9) is also shown (shaded), as well as the field defined by the products of W. Pacific off-ridge volcanism (dashed line). The trajectory of oceanic volcanic rocks erupted in the northern hemisphere which are unrelated to subduction is shown as the ‘Northern Hemisphere Reference Line (NHRL [Hart, 1984]). Significant deviations from the NHRL, especially on the $^{207}\text{Pb} / ^{204}\text{Pb}$ vs. $^{206}\text{Pb} / ^{204}\text{Pb}$ plot (Figure 21B) are commonly interpreted as due to the mixing of Pb from subducted sediments into the mantle source region. It is also noteworthy that especially the Mariana Arc lavas plot in the field of off-ridge volcanics and that subducted off-ridge volcanics and volcaniclastic rocks should also be considered as a source of Pb for IBM arc melts.

Hart [1984] used $\Delta ^{7/4}$ and $\Delta ^{8/4}$ to quantify deviations of $^{207}\text{Pb} / ^{204}\text{Pb}$ and $^{208}\text{Pb} / ^{204}\text{Pb}$ from NHRL, $\Delta > 0$ lying above NHRL and $\Delta < 0$ lying below. Because Western Pacific sediments lie above the NHRL, involvement of Pb from subducted sediments may be monitored with $\Delta ^{7/4}$. Figure 22C plots this parameter along strike of the IBM arc. The IBM arc system is characterized by a mean value of 4.4 for $\Delta ^{7/4}$, with still higher values characterizing the northernmost
is active and rapid, as shown by the steep tilts of very young sedimentary beds.

The ICZ is caused by the attempted subduction of thickened arc crust at the northeastern corner of the Philippine Sea plate. The north end of the IBM arc enters the Nankai Trough subduction zone at a rate of ~4 cm/y but the ~22 km-thick IBM crust is too thick and buoyant to be readily subducted. Instead, the northern end of IBM plows end-on into southern Honshu. This collision has been occurring in about the same place since Middle Miocene time, ~15 Ma ago [Itoh, 1986]. The deformation is partly accommodated by orocline bending of margin-parallel lithotectonic belts in southern Honshu, such as the Cretaceous-Paleogene Shimanto Belt accretionary prism [Niisuma, 1989]. The collision has rotated the Shimanto Belt from its normal ENE trend elsewhere in Honshu to a N-S and NNW-SSE trend to the west and east of the ICZ respectively. This cuspate rotation of trends that were originally more E-W is shown by the deflection of the Nankai Trough into the NNE-trending Suruga Trough on the west side of the Izu Peninsula and the NW-trending Sagami Trough on the east side (Figure 28A).

Even though the Izu Peninsula has acted for the most part as a rigid indenter during the collision, it is also being deformed and thickened. Cumulative thickening has about doubled the crustal thickness, from ~22 km for the arc at 32°15′N to ~40 km [Soh et al., 1998] in the collision zone. Collision has caused the incremental migration of the subduction zone to the south with time, manifested as major thrust faults which young from north to south. The three thrusts exposed on land (labeled 1, 2, and 3 on Figure 28) are each associated with deep, foreland-type basins which also young southwards, ranging in age from Middle Miocene in the north to Pleistocene in the south [Soh et al., 1998]. The Ashigara Basin (Figure 28A) is a good example; it filled with about 5 km of thinning- and coarsening-upwards sediments deposited between 1.6 Ma and 0.5 Ma [Soh et al., 1998]. The southernmost and youngest thrust (5 in Figure 28) lies parallel to the Zenisu Ridge on its southern flank and is associated with a broad zone of crustal seismicity [Le Pichon et al., 1987].

Uplift has exhumed the deep structural framework of the arc in the Tanzawa Mountains (Figure 28A). Exposures are made up of Tanzawa Group volcanics and sediments and the Tanzawa plutonic complex, both of Miocene age. The Tanzawa Group comprises altered basaltic and andesitic tuff, volcanic breccia and lavas, and shallow marine limestone, which is considered to be a shallow submarine volcanic sequence erupted on the IBM arc and later accreted to Honshu. The Tanzawa Group has been metamorphosed from zeolite to amphibolite facies.

Figure 28. The IBM collision zone. A) Geologic map showing the location of major thrust faults and tectonic lines (1-5 circled) and the Tanzawa Mountains. 1= Mineoka/Tonoki-Aikawa/Itoigawa-Shizuoka Thrust; 2= Tonoki-Aikawa/Nishikatsura/ Minobu Thrust; 3= Kouzus-Matsuda/Kannawa Thrust; 4= Izu-Toho Tectonic Line; 5= Zenisu-Oki Tectonic Line. Dashed line indicates incipient thrust fault. IP = Izu Peninsula; AB = Ashigara Basin. Water depth contours are labeled in km. Volcanoes are abbreviated F=Fuji, H= Hakone, Os = Oshima, Om = Omurodashi (submarine), T = Toshiba, NJ = Nii Jima, SJ = Shikine Jima, Ko = Kozushima, My = Miyakejima, Mk = Mikurajima. Underlining indicates dominantly felsic volcano. Arrow labeled '4 cm/y' indicates convergence direction and rate between IBM arc and Honshu. Note the generalized location of seismicity shallower than 50 km. Dashed line A-A' shows approximate location of section shown in B. Figure modified after Kawate and Arima [1998] and Taira et al. [1998]. B) Along-arc cross-section A-A', modified after Taira et al. [1998], showing sequence of imbrications of the IBM Superterrane. No vertical exaggeration. Scales for A and B are identical.
toward the contact with the Tanzawa plutonic complex [Soh et al., 1991]. The Tanzawa plutonic complex is interpreted as the exposed middle crust of the IBM arc and has been explicitly linked to the ~10 km thick layer with 6-6.3 km/sec velocity layer identified from the refraction profile at 32°15'N (Figure 13) [Taira et al., 1998]. K-Ar ages for biotites, hornblende, and whole rocks range from 4.6 to 10.7 Ma [Kawate and Arima, 1998].

Four intrusive stages are identified in the Tanzawa plutonic complex, a first-stage gabbro suite and three younger stages of a tonalite suite. These rocks are dominated by hornblende and plagioclase ± quartz and contain a wide range in silica, from ~44% to >70% (Figure 29A). Tanzawa plutonic rocks comprise a low-K suite similar to that of the Izu Arc; gabbroic rocks with <50% SiO₂ are likely cumulates. Trace element patterns confirm the depleted nature of Tanzawa magmas, which often have lower abundances of incompatible elements than MORB, except for enrichments in Rb, Ba, Th, and K and spikes in Pb and Sr (Figure 29B). Fields defined by Tanzawa plutonic rocks mimic those of basalts now being erupted along the magmatic front of the Izu Arc. Trace element compositions for Tanzawa felsic rocks plot in the field for volcanic arcs (Figure 29C) and arc andesite-dacite-rhyolite suites (Figure 29D). Initial ⁸⁷Sr/⁸⁶Sr for Tanzawa gabbros and tonalites (0.70331-0.70370) [Ishizaka and Tanagi, 1977] are similar to each other and to other Izu arc lavas. Tanzawa felsic rocks are comparable to abundant felsic lavas erupted along and across the Izu segment of the IBM arc. All of these geochemical parameters demonstrate that the Tanzawa igneous suite is comparable to what is expected from the igneous infrastructure of an IODC such as the northern IBM arc.

The Tanzawa plutonic complex is of special interest because of the insights it provides on the evolution of middle crust in the northern IBM arc. This has been modeled as taking place in two stages [Kawate and Arima, 1998]. The first stage was melting of amphibolite-facies low-K tholeiite in the lower crust of the IBM arc to form an intermediate melt (~60% silica). About 50% melting of amphibolite is required, at temperatures of ~1100°C and P<1.2 GPa [Nakajima and Arima, 1998]. This corresponds to conditions expected for arc crust that is less than 40 km thick; garnet is stabilized at higher pressures. They further proposed delamination of pyroxenitic residue after generation of the anatexitic melts. More siliceous melts were derived from the parental intermediate melt by fractionation of hornblende, plagioclase, and magnetite.

Figure 29. Geochemical characteristics of Tanzawa plutonic complex, all data from Kawate and Arima [1998]. A) K-Si diagram. Field occupied by volcano means from the Izu Arc (Figure 17) is shown in gray. Italicized volcanic rock names across the top (B.A. = basaltic andesite; And. = andesite) are intended as compositional guide. B) Incompatibility plot, composition of N-MORB and element order is after Hofmann [1988]. Field defined by mafic rocks (<57% SiO₂) is outlined with dashed line and that for felsic rocks (>57% SiO₂) is shaded. Izu Arc Basalt Mean is from Figure 19, note absence of data for U, Ta, and Hf. C) Tectonic discriminant diagram after Pearce et al. [1984]. Syn-COLG = syn-collisional granitoid; WPG = within-plate granitoid; ORG = ocean-ridge granitoid; VAG = volcanic arc granitoid. D) Petrogenetic diagram for adakites vs. arc andesite-dacite-rhyolite (ADR) suites, showing the composition of felsic rocks generated in equilibrium with garnet vs. those generated in equilibrium with plagioclase. Figure modified after Drummond and Defant [1990].
8. CONCLUSIONS

The IBM Subduction Factory opened for business about 50 million years ago and is now in an equilibrium state of operation. We understand the most important parts of the IBM arc system, including raw materials fed into and finished products issuing from this Subduction Factory. Inputs into the IBM Subduction Factory define an end-member assemblage of the oldest seafloor on earth which youngs northward. Sedimentary sequences on this crust are dominated by a late Mesozoic pelagic succession with a southward-thickening wedge of mid-Cretaceous volcanic and volcanioclastic rocks. Seafloor and associated supracrustal sequences are entirely subducted. Plate convergence increases from about 3 cm/year in the south to about 6 cm/year in the north. Relative convergence between the Pacific and the IBM arc system is oblique along much of the IBM trench and varies from orthogonal to margin-parallel along strike. In contrast to the situation for Pacific-Philippine Sea plate convergence, which has a pole of rotation near the southern end of the IBM arc, Philippine Sea-Eurasian plate convergence has a pole of rotation north of the IBM arc system. The clockwise rotation of the Philippine Sea plate coupled with the relatively slow subduction of the slab results in vertical sinking of the Pacific plate in the southern IBM, producing a sea-anchor force that is responsible for back-arc extension in the southern IBM. Combined effects of back-arc extension and oblique convergence result in stretching of the forearc in the south.

Along-strike variations in seafloor age and convergence rate control the shape of the subduction zone. The Wadati-Benioff zone smoothly steepens dip from 40° to 80° southwards, although earthquakes deeper than 300 km are common only beneath the Izu segment and central Marianas. Double seismic zones exist beneath the northern and southern IBM. The trajectory of subducted material can be traced with earthquakes down to a depth of about 700 km and tomographically can be outlined well into the lower mantle. In contrast, the more rapid subduction of younger, less dense oceanic lithosphere beneath northern IBM has resulted in a gentler angle of subduction and the stagnation of the subducted slab above the 660 km discontinuity. Shear-wave splitting data indicate that olivines in the mantle beneath IBM are oriented NW-SE to E-W and this is about what is expected for flow induced by NW plate convergence.

The IBM arc system is naturally divided into Izu, Bonin, and Mariana segments characterized by different morphologies, tectonic histories, and locus of outputs. The crust is about 22 km thick beneath the Izu segment and has a distinctive middle crust composed of felsic igneous rocks. The thickness and velocity structure for this arc segment is quite different from that of the central Aleutians, the only other arc for which we have a similar level of geophysical understanding. The middle crust of the IBM arc system can be studied on-land in the Izu Collision Zone, where IBM has been colliding end-on with Honshu for the past 15 Ma. The bulk crust of northern IBM contains about 56% SiO₂, much more siliceous than generally thought for IOCM, which have been thought to have basaltic bulk compositions. Further work is needed to evaluate the crustal structure beneath other parts of the arc. Back-arc basin crust of the Mariana Trough is similar in thickness to crust produced by spreading at mid-ocean ridges.

Outputs from the IBM Subduction Factory can be examined at forearc mud volcanoes and cold-water vents, along the magmatic arc, at cross-chains and in extension-related back-arc magmatic systems. Low sedimentation rates over most of the IBM arc system allow most of the forearc to be studied directly, simplifying assessments of the source of fluids issuing from vents and, incidentally providing one of the best places on the planet to study how subduction begins. The forearc mud volcanoes of southern IBM result from strong extension of this forearc and provide unique opportunities to sample slab-derived fluids, blueschists, and subducted crust, and entrained upper mantle. We speculate that the cool mantle beneath the IBM forearc may support the deepest biosphere in the planet.

The 2500-km long line of submarine and subaerial arc volcanoes provide the most spectacular output from the IBM Subduction Factory. These volcanoes erupt porphyritic and fractionated lavas, the study of which demands new techniques and approaches. There are important compositional variations along strike of the IBM arc system. The Izu segment erupts some of the most depleted arc lavas on the planet but is flanked southward by the only active shoshonitic province found along the magmatic front of an IOCM. Mariana arc lavas are less depleted than Izu arc lavas, and this may reflect an important role for subducted volcanics in the south. The Izu segment is also distinctive in having abundant submarine felsic volcanoes. Mariana arc lavas contain about 2-3% magmatic water. These lavas are characterized by distinctive depletions in Ta and Nb and enrichments in Ba, Rb, K, Pb and Sr. Isotopic tracers allow some subducted components to be unequivocally identified (e.g., water, ¹¹B, ¹³C) but not others (e.g., ⁴He, ³⁸O). Uncertainties regarding the affinities of the unmodified mantle source (MORB-like or OIB-like) complicate interpretations of other isotopic tracers. Lavas from arc cross-chains such as the Zenisu Ridge and the Kasuga seamounts indicate that the role of subducted components decreases across the arc, leading to diminished melt production with
distance from the trench. Extension-related igneous activity, localized in the Mariana Trough and the Izu rifts, provides a final perspective on IBM Subduction Factory outputs. Depending on the speed or duration of extension, IBM extensional zones may be rifting or spreading. Lavas associated with extension are primitive, glassy, and relatively straightforward to study. Rifting is associated with bimodal volcanism whereas only basalt is erupted from regions undergoing spreading. Lavas associated with backarc basin seafloor spreading contain variable amounts of water, with an average of about 1.6%; those with little water are indistinguishable from MORB whereas those with abundant water also carry a subduction component that is readily identified in trace element or isotopic signatures.

We hope that this summary and synthesis serves to motivate and guide students and scientists to help elucidate the workings of the large, complex, and deeply hidden Subduction Factory. Development of a quantitative model that explains all aspects of Subduction Factory products is our ultimate goal. A truly interdisciplinary and international effort will be required to achieve this for IBM.

Acknowledgments. We appreciate the opportunity to synthesize our understanding of the IBM arc system provided by the conveners of the Subduction Factory workshop at Eugene. We thank those who let us use their unpublished data in this synthesis: Julie Morris, Julian Pearce, Mark Reagan, and Jeff Vervoort, and to Jim Gill for pointing out some of our mistakes. We are also grateful for thoughtful reviews by John Eiler and Mark Reagan. This is UTD Geosciences contribution # 951.
